Appendix C5
Halliburton Alternative System (Delta 140 Formulation)

C1.0 Introduction

As presented in **Section 5.0** of the Hydraulic Fracturing Risk Assessment, a weight-of-evidence approach was used by Santos Ltd. (Santos) to evaluate the potential for human health and environmental (e.g., ecological) risks as a result of the hydraulic fracturing processes and the Halliburton alternative fluid system (Delta 140 formulation).

Golder Associates Pty Ltd. (Golder), on behalf of Santos, completed a qualitative risk assessment (Golder, 2013f) that evaluated the nature of the geology in the areas undergoing stimulation, the potential for impacts on water resources, the process and chemicals used.

A Quantitative Risk Assessment (QRA), completed by EHS Support, LLC (EHS Support), supplemented the qualitative risk assessment (EHS Support, 2013b). The QRA was conducted to meet Conditions 49e and 49f of the 2 October 2011 approval under the Environmental Protection and Biodiversity Conservation Act 1999 (EPBC 2008/4059) and the Environmental Amendment (EA) conditions to assess the toxicity of the mixtures.

Key reports and studies previously submitted for these fluid systems comprise:

- Golder Associates (2013f). Coal Seam Hydraulic Fracturing Risk Assessment. Human Health and Ecological Risk Assessment – Delta 140. Golder Associates Report. 1 August 2013.
- EHS Support. (2013b). Coal Seam Gas Hydraulic Fracturing Quantitative Risk Assessment Report for Halliburton Delta 140 Chemistry Report. 4 August 2013.

The QRA evaluated both the original DeltaFoam 140 and Delta 140 formulations; refer to **Appendix C2** for discussion of the results of the EHS Support QRA for the original DeltaFoam 140 fluid system.

The results and conclusions of the qualitative risk assessment components and the QRA are summarised below. Refer to the text of this report for detailed discussions on mythologies employed for each component; specific tables referred to in this summary are included for review with this document. Table numbers specific to the original reports were retained for consistency between documents.

C2.0 Qualitative Risk Assessment and Evaluation

C2.1 Chemicals Evaluated

Three 'fluid systems' were assessed, each having a foamed and non-foamed version, for a total of six hydraulic fracturing fluid mixtures. Chemical constituents identified in each hydraulic fracturing fluid system were evaluated in the hydraulic fracturing risk assessments. The list of individual chemicals is presented in **Table 1**. A mass balance of the chemicals within each of the hydraulic fracturing fluid systems is provided as **Appendix C5-1** (Table C-1; Golder, 2013f).

Information regarding the chemical and physical properties of the individual chemicals listed below can be found on the Saftey Data Sheets in **Appendix E**.

It is noted, while none of the fracturing fluid chemicals identified contain benzene, toluene, ethylbenzene, xylenes (BTEX) or polycyclic aromatic hydrocarbons (PAHs), that PAHs occur naturally in coal and it is possible that certain PAHs may naturally be present in the coal seam groundwater used in the hydraulic fracturing process.

Table 1: Hydraulic fracturing chemicals

Chemical	CAS Number
Guar Gum	9000-30-0
Acetic Acid	64-19-7
Coco dimethylaminopropyl betaine	61789-40-0
Tetrakis (hydroxymethyl) phosphonium sulphate (THPS)	55566-30-8
Sodium hydroxide [1]	1310-73-2
Crystalline silica	14808-60-7
Monoethanolamine borate	26038-87-9
Crystalline silica, quartz	14808-60-7
Hydrochloric acid	7647-01-0
Alcohols, C6-C-12, ethoxylated propoxylated	68937-66-6
Alcohols, C10-C16, ethoxylated propoxylated	69227-22-1
Choline chloride [2]	67-48-1
Ethylene glycol	107-21-1
Hemicellulase enzyme	9012-54-8
Maltodextrin	9050-36-6
Polyethylene glycol	25322-68-3
Coffee beans (green coffee bean extract; chlorogenic acid)	327-97-9
Coffee beans (caffeine)	58-08-2

1. Chemical excluded from linear gel formulation.
2. Chemical included in water formulation.

C2.2 Risk Assessment Framework and Findings

As discussed in **Section 5.0** of the systematic weight of evidence approach was utilised to complete the risk assessment for the Schlumberger fluid systems. The work has involved the following evaluations:

Qualitative Assessment Methodologies

- Environmental Hazard Assessment
- Exposure Assessment including Fate and Transport Assessment in Groundwater
- Mass Balance of the fluid systems
- Groundwater Fate and Transport Modelling.

Quantitative Risk Assessment Methodologies

- Quantitative Human Health Risk Assessment (HHRA)
- Quantitative Ecological Risk Assessment for Terrestrial and Aquatic Receptors.

C2.3 Environmental Hazard Assessment

The environmental hazard assessment approach outlined in **Section 6.1** was undertaken to rank the hydraulic fracturing chemicals based on persistence (P), bioaccumulation (B) and toxic (T) potential (hereafter referred to as PBT).

A combination of data sets were used in the PBT assessment including chemical information sheets (**Appendix E** and **Appendix G**), the Hazardous Substance Database, and modelled data from United States Environmental Protection Agency (USEPA) (2009) EPISUITE modelling software, when data not available from other sources.

Of the 18 chemicals listed above, three were not considered for PBT ranking: sodium hydroxide and hydrochloric acid due to their propensity to readily dissociate; crystalline silica due to its similarity to sand, which is used as a proppant. Physico-chemical and/or toxicological data were not available, and surrogates could not be identified for maltodextrin (9050-36-6). Limited toxicological data were available for polyethylene glycol (25322-68-3) and guar gum (9000-30-0); however, physico-chemical data were lacking for these constituents. Therefore, they were ranked solely on their respective toxicity data.

C2.4 Summary of Qualitative PBT and Human Toxicity Assessment

In accordance with the methodology outlined in **Section 6.1**, eighteen chemicals identified in the Halliburton alternative fluid system (Delta 140) were assessed for their potential persistence, bioaccumulation and toxicity in the PBT assessment. None of the chemicals was considered to be a PBT substance.

C2.5 Exposure Assessment

As discussed in **Section 7.0**, the exposure assessment identified receptors potentially exposed to COPCs identified for the study and outlines the exposure pathways by which the receptors may come in to contact with the COPCs. A detailed exposure assessment was not conducted in the qualitative risk assessment; however, hazards from potential exposures were determined to be primarily occupational concerns with some limited environmental matters (Golder, 2013f).

C2.6 Mass Balance of Fluid System

A quantitative mass balance calculation was undertaken to identify the amount of each chemical additive of the hydraulic fracturing fluid in the following fluid systems:

- Delta 140
- Linear Gel

- Water
- Acid.

The results of the mass balance calculations are presented in the referenced Table C-1 (Golder, 2013f) which is included in **Appendix C5-1**.

C2.7 Fate and Transport Modelling

As discussed in **Section 7.2** fate and transport modelling was conducted on key constituents of interest in the hydraulic fracturing fluid systems. These results provided the framework for assessing potential mobility of all constituents used in hydraulic fracturing. The modelling demonstrated that there is limited potential for chemicals to migrate within the coal seams. Refer to **Section 7.2** for further detail.

C3.0 Quantitative Risk Assessment

In accordance with the methodologies presented in **Section 8.0**, a QRA was conducted on a theoretical dataset for those chemicals identified in the Golder Human Health and Ecological Risk Assessment (EHS Support, 2013b). The QRA approach evaluates the toxicity of the individual substances and characterises the cumulative risks of the total effluent toxicity and ecotoxicity.

Generally, this methodology includes the identification of the hazards posed by constituents in the flowback water, compilation of the toxicity criteria for each constituent, development of exposure models to estimate the daily intake of the constituents, and calculations of individual constituent hazard quotients (daily intake divided by the toxicity criteria) and a cumulative constituent hazard index (HI) for each potentially complete exposure pathway for each human or terrestrial receptor.

Potential complete exposure pathways to the storage of flowback from hydraulically stimulated wells and potential risks to humans, terrestrial and aquatic receptors from the potential storage and accidental releases are evaluated in the QRA.

No further assessment of groundwater was determined to be necessary due to lack of potentially complete exposure pathways. Detailed operational procedures have been provided that are designed to contain the hydraulic fracturing fluids within the coal sequences, and no connection exists between groundwater in the coal seams and surface-water or springs (and therefore Matters of National Environmental Significance [MNES]). Further, the potential risks to workers involved with the hydraulic fracturing process were not considered as detailed Health and Safety (H&S) procedures are employed to manage exposures. The QRA considered the following specific exposure pathways:

1. Exposure of trespassers to flowback water contained within flowback storage ponds.
2. Exposure of terrestrial receptors (e.g., livestock and wildlife) to flowback water contained within the flowback storage ponds.
3. Exposure of aquatic receptors to flowback water in the situation of an accidental release, such as from piping or a release from the flowback storage pond. These potential releases could include a failure of containment systems, overtopping of the dam or in an extreme situation (considered highly unlikely) structural failure of the dam itself.

C3.1 Exposure Assessment

The purpose of the exposure assessment in the QRA was to predict the magnitude and frequency of potential human exposure to each COPC following the methodologies presented in **Section 8.1**. A conceptual site model (CSM) was developed which describes the potential receptors and exposure scenarios for the flowback water used in this exposure assessment. The potential exposures to receptors were evaluated based on the potential for a complete exposure pathway.

As discussed in **Section 8.3**, exposure point concentrations (EPCs) were derived for the theoretical assessment; empirical data were not available for evaluation. The EPCs for the theoretical assessment were calculated by estimating the mass and discharge flow of the COPCs from the flowback water monitoring data were used **Appendix C5-2** (Appendix C, Table C-2; EHS Support, 2013b).

C3.2 Human Health QRA

A human health hazard assessment was conducted according to the methodologies presented in **Section 8.4**. The purpose of the hazard assessment process was to summarise the environmental data, and to address the toxicological assessment of the COPCs that will be evaluated further in the risk assessment process.

Exposure assumptions for the human trespasser scenario were developed based on default or site-specific assumptions (**Section 8.4**). This receptor exposure pathway includes a small child to teenager that may come in contact with the above grade water exposure scenario for approximately 20 days/year for a 10-year period with potential incidental ingestion (of 50 millilitre [mL] water) and dermal contact (e.g., swimming where the whole body gets wet) for one half hour (Table 3; EHS Support, 2013b, attached).

Calculation of intake of COPCs was performed using the equations presented below:

Ingestion of water:

$$Intake\ (mg/kg-day)\ =\ (CW\ x\ IR\ X\ EF\ X\ ED)\ /\ (BW\ x\ AT)$$

Dermal contact with water:

$$Absorbed\ dose\ (mg/kg-day)\ =\ (CW\ x\ SA\ x\ DP\ x\ ET\ x\ EF\ x\ ED\ x\ CF)\ /\ (BW\ x\ AT)$$

Where:

CW = concentration in water (mg/l)
ET = exposure time (hr/day or hours/hours)
EF = exposure frequency (day/year)
ED = exposure duration (years)
CF = correction factor (1 x 10-3 l/cm3)
AT = averaging time (days)
IR = ingestion rate (l/hr)
BW = body weight (kg)
SA = skin surface area available for contact (cm2/d)
DP = dermal permeability factor (Kp – cm/hr)

C3.3 Toxicity Assessment

A toxicity assessment was conducted to determine the relationship between the dose of a COPC taken into the body, and the probability that an adverse effect will result from that dose. Quantitative estimates of the potency of COPCs include two sets of toxicity values, one for genotoxic carcinogens and one for other non-genotoxic carcinogens and non-carcinogenic effects. As discussed in **Section 8.4,** detailed toxicological profiles were developed for the chemicals. The toxicological profiles are included as **Appendix F**.

The assessment of toxicity of the COPCs was used to develop initial screening criteria for human health exposure scenarios as discussed in **Section 8.4**. Refer to Tables 1 and 2 of the EHS Support QRA for details regarding the toxicity assessment of the COPCs (EHS Support, 2013b).

C3.4 Risk Estimation

Risk estimation was performed in accordance with the methodologies outlined in **Section 8.4**. The total target risk range for carcinogens was 1 x 10^{-4} to 1 x 10^{-6}; the target HI for non-threshold effects is less than or equal to 1.0.

No carcinogenic compounds are present in the stimulation fluids injected into the subsurface and as a result, only non-carcinogenic risks were calculated. The exposure scenarios include the specific fracturing fluids event from Golder (2013f) Table C-1, attached, for the 20 and 80 percent (%) mass recovery from the fracturing fluid well flowback. The modelled risks from injected chemicals in the flowback water at 20 % mass recovery were acceptable (HI=0.94); the modelled risks to the trespasser for the maximum exposure to COPCs at the 80 % recovery predicted a HI of 3.8 (Tables 6 and 7; EHS

Support, 2013b, attached). The primary risk drivers for this scenario were coco dimethylaminopropyl betaine and THPS via incidental ingestion, and C6-C12 ethozylanted propoxylated alcohols via dermal contact.

Based on field observations, the risk assessment conducted on 80 % mass recovery in the flowback water diverted to the flowback storage ponds, is highly conservative. These conditions are not observed in the fields as the combination of biodegradation and sorption in the subsurface and biodegradation, complexation and settling of suspended solids in the flowback storage ponds results in lower concentrations. Based on stimulation flowback monitoring conducted by Santos and the QRA completed for the Schlumberger fluid systems (EHS Support, 2013b), 20 % of the total mass of constituents injected is assumed to be recovered in the flowback water. On this basis and using the theoretical concentrations, no adverse effects are predicted on trespassers.

C3.5 Ecological Risk Assessment

As discussed in **Section 8.5**, a screening level ecological risk assessment (ERA) was conducted to evaluate the potential for adverse ecological effects to terrestrial and aquatic ecological receptors that may be exposed to residual levels of hydraulic fracturing fluids in surface water used in the coal seam gas (CSG) fields.

Terrestrial receptors evaluated in the ERA include domesticated livestock, large mammalian wildlife and small mammalian wildlife. Beef cattle were used to evaluate domesticated livestock, kangaroos evaluated for large mammalian wildlife, and dingos for small mammalian wildlife. Aquatic receptors evaluated included invertebrates and fishes.

Ecological effects were characterised following the methodologies outlined in **Section 8.5.3** (Table 8; EHS Support, 2013b, attached). Exposure scenarios were the same for ecological receptors as human receptors; EPCs were estimated in accordance with the methodology presented in **Section 8.5.4** (**Appendix C5-3**; Table A-2; EHS Support, 2013b). Environmental fate information is provided in Table 9 (EHS Support, 2013b), attached.

Risks were characterised in accordance with the methodologies discussed in **Section 8.5.5**. The resulting ecological hazard quotient must be less than or equal to 1.0 for risks to be considered acceptable.

C3.5.1 Estimation of Risk

The HI calculated for flowback water for aquatic risk were elevated above the acceptable level for the majority of COPCs evaluated (**Appendix C2-2**, Table C-4; EHS Support, 2013b). Where large discharges of flowback water occur to surface water and/or flux dilution within the surface-water was insufficient, potential impacts on aquatic receptors could occur. As noted in the toxicity assessment section above, the lack of a robust aquatic toxicological database resulted in aquatic screening values for the theoretical exposure scenario COPCs to be conservatively very low.

The modelled risks from injected chemicals in the flowback water were all acceptable for each of the ecological receptors modelled, except livestock cattle for the maximum exposure to COPCs at the 80 % recovery indicating a HI equal to 2.0 (Tables 15 and 6, 19 and 20, 23 and 24; EHS Support, 2013b, attached). Primary risk drivers were coco dimethylaminopropyl betaine and THPS via incidental ingestion. As discussed in the HHRA, 80 % recovery conditions are not observed in the fields. A recovery of 20 % is more realistic based on stimulation flowback monitoring conducted by Santos (EHS Support, 2013b).

C4.0 Summary of QRA Findings

The QRA was completed as discussed in **Section 8.0**. An assessment was conducted using highly conservative theoretical calculations based on the chemicals utilised by Halliburton in hydraulic fracturing. This assessment assumed that a range of theoretical percentages of injected chemicals would be present in the flowback water.

Consistent with the risk assessment and groundwater fate and transport modelling conducted by Golder, no potentially complete exposure pathways were identified for groundwater. Potential exposures are limited to the aboveground storage and handling of flowback water as part of the CSG Water Management Plan (WMP). Management of CSG water involves the temporary storage of flowback water in flowback storage ponds.

On the basis of the quantitative risk calculations, the potential risks associated with the flowback water are generally limited. Potential risks to trespassers could occur with repeated exposures to flowback water. However, the cumulative risks are only slightly above the non-carcinogenic threshold discussed above where management and operational controls can be implemented to control potential exposures. There were no carcinogenic risks identified.

Limited to no risks to cattle and native mammals were identified in the risk assessment; and only in the most conservative theoretical calculations (80 % chemical mass in the flowback water) were potentially unacceptable risks identified. Based on contractor experience and stimulation flowback monitoring, 20 % of the total mass constituents injected is assumed to be recovered in flowback water. Additionally, environmental fate information indicated primary risk drivers are readily biodegradable. Therefore, no potential risks exist for livestock or native mammals.

Similarly, potential impacts could occur if releases of flowback water were to occur to aquatic environments. Based on the use of clay liners and operational controls that limit the potential for turkey's nest and dam overflows, the potential for these risks are also considered limited.

A combination of management and operational controls are being implemented to eliminate and control the potential for exposures. These include:

- Worker training and hazard identification
- Use of appropriate personal protective equipment (gloves, etc.)
- Flowback storage pond fencing to prevent entry of livestock and minimise trespassing
- Installation of clay dam liners and routine dam inspections to prevent releases from flowback storage ponds
- Routine operational and security patrols to prevent trespassing.

C5.0 . Conclusions

A weight-of-evidence evaluation of potential risks as described in **Section 5.0** was performed for the Halliburton alternative fluid system (Delta 140). Based on the qualitative and quantitative risk characterisations, the overall risk to human health and the environment is low. Existing operational control activities employed by Santos are in place that will limit the potential risks to human health and the environment. These measures include:

- Occupational health and safety procedures implemented during hydraulic fracturing operations to prevent workers from direct contact with chemicals during spills and when handling flowback water or sediments;
- Environmental authority conditions that preclude the construction of well pads within 100 metres of a watercourse of water body.
- Implementation of spill containment procedures during operations to prevent migration of and exposure to chemicals;
- Disposal or capping of sediments contained within drained mud pits and turkey nests , to prevent exposure to contaminates in windborne dust;
- Fencing of drill pads to prevent trespassers and installation of signs to indicate that the water in the turkeys nest and mud pit is not potable and may contain contaminants;
- Installation and maintenance of fences around the well pad to prevent access to the drill pad by livestock and large native fauna;
- Santos operational procedures to ensure well integrity and design of fracture to stay within the target seam; and
- Mud pits and turkeys nests with clay liners, or similar material, to prevent seepage of flowback water into underlying aquifers.

Regular monitoring of water supply bores and surface water for a representative suite of chemicals within 2 kilometre of wells that are fractured is required to confirm the conclusion of incomplete exposure pathways and low risk.

No additional risks, other than those previously discussed, were identified with the chemicals or systems employed by Halliburton in hydraulic fracturing. Evaluation of other potential risks associated with hydraulic fracturing (i.e., noise and vibration) was conducted. Refer to **Section 9.0** for methodology specifics and results of this evaluation.

Notes:

Constituent mass and concentration calculations for Delta 140 and Linear Gel assume a conservative "typical" 50,000 gallon (189,271 L) fluid mixture. Water, proppant and additive mass may vary to accommodate site-specific requirements.

Constituent mass and concentration calculations for Water and Acid assume a 1000 gallon (3785 L) fluid mixture. Fluid volume and additive mass may vary to accommodate site-specific requirements.

Formulation reflects Delta 140 foamed version (maximum additives). Non-foamed version excludes coco dimethylaminopropyl betaine.

Appendix C5-2

Appendix C6
Schlumberger YF120Flex with J318 System

C1.0 Introduction

As presented in **Section 5.0** of the Hydraulic Fracturing Risk Assessment, Santos Ltd. (Santos) used a weight-of-evidence approach to evaluate the potential for human health and environmental (e.g., ecological) risks as a result of the hydraulic fracturing processes and the Schlumber YF120Flex with J318 System.

Golder Associates Pty Ltd. (Golder), on behalf of Santos, completed a qualitative risk assessment (Golder, 2013c) that evaluated the nature of the geology in the areas undergoing stimulation, the potential for impacts on water resources, the process and chemicals used and the potential risks associated with chemicals and backflow water handled and stored above grade.

EHS Support, LLC (EHS Support) conducted a persistence, bioaccumulation and toxicity (PBT) assessment and and a Quantitative Risk Assessment (QRA) to meet Conditions 49e and 49f of the 2 October 2011 approval under the *Environmental Protection and Biodiversity Conservation Act 1999* (EPBC 2008/4059) and the Environmental Amendment (EA) conditions to assess the toxicity of the mixtures.

The results and conclusions of the qualitative risk assessment components and the QRA are presented below. Refer to **Section 6.0** through **Section 8.0** for detailed discussions on the methodologies employed for the qualitative risk assessment and QRA components, which are referenced in the sections below.

C2.0 Qualitative Risk Assessment and Evaluation

C2.1 Chemicals Evaluated

The Schlumberger YF120Flex with J318 'fluid system' was assessed. The list of individual chemicals is presented in **Table 1** below. A mass balance of the chemicals is provided as **Appendix C6-1**. Information regarding the chemical and physical properties of the individual chemicals listed below are included in **Appendix E** and **Appendix G** of this report.

While none of the fracturing fluid chemicals identified contain benzene, toluene, ethylbenzene, xylenes (BTEX) or polycyclic aromatic hydrocarbons (PAHs), PAHs occur naturally in coal and it is possible that certain PAHs may naturally be present in the coal seam groundwater used in the hydraulic fracturing process.

Table 1: Hydraulic fracturing chemicals

Chemical	CAS Number
Crystalline silica	14808-60-7
Guar gum	9000-30-0
Potassium borate	1332-77-0
Cholinium chloride	67-48-1
2,2`,2"-nitrilotriethanol	102-71-6
Diammonium peroxidisulphate	7727-54-0
Diatomaceous earth, calcined	91053-39-3
Magnesium nitrate	10377-60-3
Potassium hydroxide	1310-58-3
Glycerol	56-81-5
Hydrochloric acid	7647-01-0
Cristobalite	14464-46-1
Non-crystalline silica	7631-86-9
5-chloro-2-methyl-2h-isothiazolol-3-one	26172-55-4
Magnesium chloride	7786-30-3
Magnesium silicate hydrate (talc)	14807-96-6
2-methyl-2h-isothiazol-3-one	2682-20-4
Vinylidene chloride/methylacrylate copolymer	25038-72-6

C2.2 Risk Assessment Framework and Findings

As discussed in **Section 5.0**, a systematic weight of evidence approach was utilised to complete the risk assessment for the Schlumberger fluid systems. The work has involved the following evaluations:

Qualitative Assessment Methodologies

- PBT Assessment
- Exposure Assessment
- Mass Balance of Fluid System
- Fate and Transport Modeling.

Quantitative Risk Assessment Methodologies

- Quantitative Human Health Risk Assessment (HHRA)
- Quantitative Ecological Risk Assessment for Terrestrial and Aquatic Receptors.

C2.3 PBT Assessment

The PBT approach outlined in **Section 6.1** was undertaken to rank the hydraulic fracturing chemicals based on persistence (P), bioaccumulation (B) and toxic (T) potential (**Appendix G**). As a result of this assessment, no chemical constituents identified in the YF120Flex with J318 fluid system were classified as a PBT chemical and are therefore not considered to be inherently hazardous. The results of the PBT Assessment are presented in **Table 2**, attached.

C2.4 Exposure Assessment

As discussed in **Section 7.0**, the exposure assessment identified receptors potentially exposed to chemicals of potential concern (COPC) identified for the study and outlines the exposure pathways by which the receptors may come in to contact with the COPCs. A detailed exposure assessment was not conducted in the qualitative risk assessment.

C2.5 Mass Balance of Fluid System

A quantitative mass balance calculation was undertaken to identify the amount of each chemical additive of the hydraulic fracturing fluid system. The results of the mass balance calculations are presented in **Appendix C6-1**.

C2.6 Fate and Transport Modelling

As discussed in **Section 7.2**, fate and transport modelling was conducted on a range of key constituents of interest in typical hydraulic fracturing fluid systems. These results provided the framework for assessing potential mobility of all constituents used in hydraulic fracturing. The modelling demonstrated that despite the variability in chemical properties between fluid systems there is limited potential for chemicals to migrate within the coal seams. Refer to **Section 7.2** for further detail.

C3.0 Quantitative Risk Assessment

In accordance with the methodologies presented in **Section 8.0**, a QRA was conducted on theoretical datasets for those chemicals identified in the YF120Flex with J318 fluid system. The QRA approach evaluates the toxicity of the individual substances and characterises the cumulative risks of the total effluent toxicity and ecotoxicity.

Generally, this methodology includes the identification of the hazards posed by constituents in the flowback water, compilation of the toxicity criteria for each constituent, development of exposure models to estimate the daily intake of the constituents, and calculations of individual constituent hazard quotients (daily intake divided by the toxicity criteria) and a cumulative constituent hazard index (HI) for each potentially complete exposure pathway for each human or terrestrial receptor.

Potential complete exposure pathways to the storage of flowback from hydraulically stimulated wells and potential risks to humans, terrestrial and aquatic receptors from the potential storage and accidental releases are evaluated in the QRA.

No further assessment of groundwater was determined to be necessary due to lack of potentially complete exposure pathways. Detailed operational procedures have been provided that are designed to contain the hydraulic fracturing fluids within the coal sequences, and no connection exists between groundwater in the coal seams and surface-water or springs (and therefore Matters of National Environmental Significance [MNES]). Further, the potential risks to workers involved with the hydraulic fracturing process were not considered as detailed Health and Safety (H&S) procedures are employed to manage exposures. The QRA considered the following specific exposure pathways:

1. Exposure of trespassers to flowback water contained within flowback storage ponds.
2. Exposure of terrestrial receptors (e.g., livestock and wildlife) to flowback water contained within the flowback storage ponds.
3. Exposure of aquatic receptors to flowback water in the situation of an accidental release, such as from piping or a release from the flowback storage pond. These potential releases could include a failure of containment systems, overtopping of the dam or in an extreme situation (considered highly unlikely) structural failure of the dam itself.

C3.1 Exposure Assessment

The purpose of the exposure assessment in the QRA was to predict the magnitude and frequency of potential human exposure to each COPC following the methodologies presented in **Section 8.1**. A conceptual site model (CSM) was developed which describes the potential receptors and exposure scenarios for the flowback water used in this exposure assessment. The potential exposures to receptors were evaluated based on the potential for a complete exposure pathway.

As discussed in **Section 8.3**, exposure point concentrations (EPCs) were derived for the theoretical assessment; empirical data were not available for evaluation. The EPCs for the theoretical assessment were calculated by estimating the mass and discharge flow of the COPCs in the flowback water.

C3.2 Human Health QRA

A human health hazard assessment was conducted according to the methodologies presented in **Section 8.4**. The purpose of the hazard assessment process was to summarise the environmental data, and to address the toxicological assessment of the COPCs that will be evaluated further in the risk assessment process.

Exposure assumptions for the human trespasser scenario were developed based on default or site-specific assumptions (**Section 8.4**). This receptor exposure pathway includes a small child to teenager that may come in contact with the above grade water exposure scenario for approximately 20 days/year for a 10-year period with potential incidental ingestion (of 50 millilitres [ML] of water) and dermal contact (e.g., swimming where the whole body gets wet) for one half hour. The exposure parameters used in the QRA are presented on **Table 3**, attached.

Calculation of intake of COPCs was performed using the equations presented below:

Ingestion of water:

$$Intake\ (mg/kg-day)\ =\ (CW\ x\ IR\ X\ EF\ X\ ED)\ /\ (BW\ x\ AT)$$

Dermal contact with water:

$$Absorbed\ dose\ (mg/kg-day)\ =\ (CW\ x\ SA\ x\ DP\ x\ ET\ x\ EF\ x\ ED\ x\ CF)\ /\ (BW\ x\ AT)$$

Where:

CW = concentration in water (mg/l)
ET = exposure time (hr/day or hours/hours)
EF = exposure frequency (day/year)
ED = exposure duration (years)
CF = correction factor (1 x 10-3 l/cm3)
AT = averaging time (days)
IR = ingestion rate (l/hr)
BW = body weight (kg)
SA = skin surface area available for contact (cm2/d)
DP = dermal permeability factor (Kp – cm/hr).

C3.3 Toxicity Assessment

A toxicity assessment was conducted to determine the relationship between the dose of a COPC taken into the body, and the probability that an adverse effect will result from that dose. Quantitative estimates of the potency of COPCs include two sets of toxicity values, one for genotoxic carcinogens and one for other non-genotoxic carcinogens and non-carcinogenic effects. As discussed in **Section 8.4,** detailed toxicological profiles were developed for the chemicals. The toxicological profiles are included as **Appendix F**.

The assessment of toxicity of the COPCs was used to develop initial screening criteria for human health exposure scenarios as discussed in **Section 8.4**. The derivation of Oral Reference Dose and Drinking Water Guideline Values are presented in **Table 4**, attached, and the Australian Drinking Water Screening Values are presented inn **Table 5**, attached.

C3.4 Exposure Point Concentration

As presented above, the exposure scenarios are based on anticipated conditions, and the potential for exposure to the theoretical estimate of exposure. EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations and the existing environmental conditions within the fracturing fluids sump or mud pit, and the flowback storage ponds.

For the theoretical calculations, the mass and estimated chemical concentrations of the COPCs in the YF120Flex with J318 fluids, as presented in **Appendix C6-1**, were used to estimate the potential concentrations in water within the fracturing fluids sump or flare pit, or flowback storage ponds. Based on stimulation flow back monitoring conducted by Santos and the QRA completed for the Schlumberger

Fluid Systems (**Appendix C**), 20 percent (%) of the total mass of constituents injected is assumed to be recovered in the flowback water. This mass is diluted within 150% of the injected volume (the minimum volume that must be flowed back) to establish an "estimated" concentration (i.e., concentration expected due to full dilution of the back flow water) within the flowback storage ponds.

The flowback water will be contained within the flowback storage ponds for a projected maximum period of one year of operational activity before transfer or conveyance to the water treatment facilities. Therefore, the concentration of COPCs in the flowback storage pond water was adjusted, where applicable, to account for the biodegradation and photolytic degradation of constituents over time. The biodegradation information was obtained from the Organisation for Economic Cooperation and Development (OECD) ready tests (OECD, 1992) that were developed as a first-tier testing scheme to provide preliminary screening of organic chemicals. The ready tests are stringent screening tests that are conducted under aerobic conditions in which a high concentration of the test substance is used, and biodegradation is measured by non-specific parameters including dissolved organic carbon, biochemical oxygen demand and carbon dioxide production. **Table 6**, attached, presents the environmental fate information that was used to assess biodegradation of COPCs, and that was applied at the time periods of 0, 30, 150 and 300 days from initial flowback.

The water quality data derived using these assumptions for the theoretical COPCs are presented in **Appendix C6-1**.

The theoretical EPCs for the four exposure time periods (0, 30, 150 and 300 days) were compared to human health toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Appendix C6-2**.

C3.5 Risk Estimation

Risk estimation was performed in accordance with the methodologies outlined in **Section 8.4**. The total target risk range for carcinogens was 1×10^{-4} to 1×10^{-6}; the target HI for non-threshold effects is less than or equal to 1.0.

No carcinogenic compounds are present in the stimulation fluids injected into the subsurface and as a result, only non-carcinogenic risks were calculated.

The results of the theoretical assessments for YF120Flex with J318 fluid systems for the trespasser exposure scenarios (day 0 and day 150, YF120Flex with J318 events) are summarized in **Tables 7** and **8**, attached. As discussed above, the theoretical assessment was only conducted at the well pad sites.

The exposure scenarios include the YF120Flex with J318 fluid system event, as presented in **Appendix C6-1** for day 0 and day 150 from the flowback storage pond. The trespasser for day 0 did not have unacceptable risks for the YF120Flex with J318 fluid system (HI=0.49, **Table 7**, attached). The trespasser for day 150 did not have unacceptable risks for the YF120Flex with J318 fluid system (HI=0.47, **Table 8**, attached).

On this basis and using the theoretical concentrations, no adverse effects are predicted on trespassers.

C3.6 Ecological Risk Assessment

As discussed in **Section 8.5**, a screening level ecological risk assessment (ERA) was conducted to evaluate the potential for adverse ecological effects to terrestrial and aquatic ecological receptors that may be exposed to residual levels of hydraulic fracturing fluids in surface water used in the coal seam gas (CSG) fields.

C3.7 Exposure Assessment

Terrestrial receptors evaluated in the ERA include domesticated livestock, large mammalian wildlife and small mammalian wildlife. Beef cattle were used to evaluate domesticated livestock, kangaroos evaluated for large mammalian wildlife, and dingos for small mammalian wildlife. Aquatic receptors evaluated included invertebrates and fishes.

The estimate for dose-based or intake rates for the assessment endpoints for wildlife representing domestic livestock and native mammalian species used the following general equation:

TI = Cwater x IRwater x EF x ED / BW x ED x 365 days/year

Where:

TI = Total intake of COPC (mg/kg/day)
Cwater = Concentration of COPC in water (mg/l)
IRwater = Ingestion rate (litres/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
BW = Body weight (kg).

The exposure assumptions are presented in **Tables 9** through **11**.

C3.8 Toxicity Assessment

To evaluate the potential for adverse ecological effects, toxicity reference values (TRVs) are selected as measurement endpoints for the ERA that will be used in the risk analysis. The TRVs are based on COPC levels that imply no adverse effects or levels that represent the lowest concentration at which adverse effects may occur. The ERA used two types of TRVs. The first TRV is a concentration-based TRV to evaluate the concentration of the selected COPC in the surface water and direct exposure by the aquatic ecological receptor. The determination of TRVs for freshwater was conducted according to the predicted no-effects concentration (PNEC) guidance in the Environmental Risk Assessment Guidance Manual for Industrial Chemicals prepared by the Australian Environmental Agency (AEA, 2009). As discussed in **Section 8.4**, detailed environmental profiles were developed for the chemicals. The environmental profiles are included in the risk dossiers in **Appendix G**. **Table 12**, attached, presents the COPC, the endpoint, NOEC [milligrams per litre (mg/L)], assessment factor and the aquatic PNEC (mg/L). The second TRV is a dose-based TRV to evaluate the intake dose of the selected COPC from exposure to surface water by ingestion. The calculated TRVs for each of the mammalian ecological receptors evaluated in the ERA are presented in the species-specific ecological risk models.

C3.9 Exposure Point Concentration

EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations. The potentially affected flowback water that represents complete exposure pathways for the ecological receptors includes the surface water systems (e.g., flowback storage ponds and mud pits) that were used to estimate the EPCs for the human health receptors. Similar to the EPCs for the human health receptors, the EPCs for the ecological receptors assumed 20 % of mass returned in the flowback water was diluted within 150 % of the injected volume of return water, and was then adjusted based on biodegradation rates to calculate the theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days). **Appendix C6-1** presents the calculated EPCs for the ecological receptor exposure scenarios. The theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days) were compared to ecological based toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Appenidix C6-3**.

Risks were characterised in accordance with the methodologies discussed in **Section 8.5.6**. The resulting ecological hazard quotient must be less than or equal to 1.0 for risks to be considered acceptable.

C3.10 Estimation of Risk

The HI calculated for flowback water for aquatic risk were elevated above the acceptable level for the majority of COPCs evaluated (**Appendix C6-3**). Where large discharges of flowback water occur to surface water and/or flux dilution within the surface-water was insufficient, potential impacts on aquatic receptors could occur. As noted in the toxicity assessment section above, the lack of a robust aquatic toxicological database resulted in highly conservative aquatic screening values for the theoretical exposure scenario COPCs to be conservatively very low.

The results of the theoretical assessments for YF120Flex with J318 fluid systems for the livestock cattle, kangaroo and dingo are summarized in **Tables 13** through **18**, attached. The exposure scenarios include the YF120Flex with J318 fluid systems EPCs presented in **Appendix C6-1** for day 0 and day 150 from the fracturing fluid well flowback. The modelled risks from YF120Flex with J318 fluid system chemicals in the flowback water were unacceptable for the livestock cattle (HI=6.8 to 6.9, **Table 13** and **14**, attached) and kangaroo (HI=1.4, **Table 15** and **16**, attached) for both exposure scenarios. The primary risk driver was potassium borate via incidental ingestion. The modelled risks from YF120Flex with J318 fluid system chemicals in the flowback water were acceptable for the dingo (HI=0.58 to 0.57, **Table 17** and **18**, attached) for both exposure scenarios.

C4.0 Summary of QRA Findings

The QRA was completed as discussed in **Section 8.0**. An assessment was conducted using highly conservative theoretical calculations based on the chemicals utilised by Schlumberger in hydraulic fracturing. This assessment assumed that a range of theoretical concentrations of injected chemicals would be present in the flowback water based on biodegradation rates, where applicable.

Consistent with the risk assessment and groundwater fate and transport modelling conducted by Golder, no potentially complete exposure pathways were identified for groundwater. Potential exposures are limited to the aboveground storage and handling of flowback water as part of the CSG Water Management Plan (WMP). Management of CSG water involves the temporary storage of flowback water in flowback storage ponds.

The results of the qualitative PBT Assessment indicated that no chemical constituents identified in the YF120Flex with J318 fluid system was classified as a PBT chemical and therefore fluids containing these chemicals are not considered inherently hazardous.

The two exposure scenarios modelled for the QRA were 20 % flowback return, and either 0 or 150-day retention with EPC based on applicable degradation rates. Based on quantitative risk calculations, the potential risks to the trespasser associated with the flowback water are acceptable. There were no carcinogenic risks identified.

The modelled risks from YF120Flex with J318 fluid system chemicals in the flowback water were unacceptable for the livestock cattle and kangaroo for both exposure scenarios. The primary risk driver was potassium borate via incidental ingestion. Potential risks to the dingo were acceptable for both exposure scenarios.

Similarly, potential impacts could occur if releases of flowback water were to occur to aquatic environments. Based on the use of low permeability materials (clay liners) and operational controls that limit the potential for turkey nest and dam overflows, the potential for these risks are also considered limited.

A combination of management and operational controls are being implemented to eliminate and control the potential for exposures. These include:

- Worker training and hazard identification
- Use of appropriate personal protective equipment (gloves, etc.)
- Flowback storage pond fencing to prevent entry of livestock and native fauna and minimise trespassing
- Use of low permeability materials or dam liners and routine dam inspections to prevent releases from flowback storage ponds
- Routine operational and security patrols to prevent trespassing.

C5.0 Conclusions

A weight-of-evidence evaluation of potential risks as described in **Section 5.0** was performed for the Schlumberger YF120Flex with J318 fluid system. Based on the qualitative and quantitative risk characterisations, the overall risk to human health and the environment is low. Existing operational control activities employed by Santos are in place that will limit the potential risks to human health and the environment. These measures include:

- Occupational health and safety procedures implemented during hydraulic fracturing operations to prevent workers from direct contact with chemicals during spills and when handling flowback water or sediments;
- Environmental authority conditions that preclude the construction of well pads within 100 metres of a watercourse of water body;
- Implementation of spill containment procedures during operations to prevent migration of and exposure to chemicals;
- Disposal or capping of sediments contained within drained mud pits and turkey nests , to prevent exposure to contaminates in windborne dust;
- Fencing of drill pads to prevent trespassers and installation of signs to indicate that the water in the turkeys nest and mud pit is not potable and may contain contaminants;
- Installation and maintenance of fences around the well pad to prevent access to the drill pad by livestock and large native fauna;
- Santos operational procedures to ensure well integrity and design of fracture to stay within the target seam; and
- Mud pits and turkeys nests with clay liners, or similar material, to prevent seepage of flowback water into underlying aquifers.

Regular monitoring of water supply bores and surface water for a representative suite of chemicals within 2 kilometre of wells that are fractured is required to confirm the conclusion of incomplete exposure pathways and low risk.

No additional risks, other than those previously discussed, were identified with the chemicals or systems employed by Schlumberger in hydraulic fracturing. Evaluation of other potential risks associated with hydraulic fracturing (i.e., noise and vibration) was conducted. Refer to **Section 9.0** for methodology specifics and results of this evaluation.

Crystalline Silica	Water-insoluble mineral; not biodegradable
Guar Gum	Readily biodegradable (half-life = 15 days)a
Potassium borate	Water-soluble inorganic; (borate): not biodegradable
Cholinium chloride	Readily biodegradable (half-life = 15 days)a
2,2′,2″-nitrilotriethanol	Readily biodegradable (half-life = 15 days)a
Diammonium peroxidisulphate	Dissociates completely in aqueous media
Potassium hydroxide	Dissociates completely in aqueous media
Glycerol	Readily biodegradable (half-life = 15 days)a
Hydrochloric acid	Dissociates completely in aqueous media
Vinylidene chloride/methacrylate copolymer	Polymer; not biodegradable
Diatomaceous earth, calcined	Water-insoluble mineral; not biodegradable
Magnesium nitrate	Dissociates completely in aqueous media
Non-crystalline silica	Water-insoluble mineral; not biodegradable
5-chloro-2-methyl-2h-isothazolo-3-one/2-methyl-2h-isothiasol-3-one [3:1]	Half-lives in river water-sediment system are 17.3 and 9.1 hours, respectively.
Magnesium silicate hydrate (talc)	Water-insoluble mineral; not biodegradable
Magnesium chloride	Dissociates completely in aqueous media
Cristobalite	Water-insoluble mineral; not biodegradable

Santos

Appendix C7
Schlumberger Sapphire LF System

C1.0 Introduction

As presented in **Section 5.0** of the Hydraulic Fracturing Risk Assessment, Santos Ltd. (Santos) used a weight-of-evidence approach to evaluate the potential for human health and environmental (e.g., ecological) risks as a result of the hydraulic fracturing processes and the Schlumber Sapphire LF System.

Golder Associates Pty Ltd. (Golder), on behalf of Santos, completed a qualitative risk assessment (Golder, 2013c) that evaluated the nature of the geology in the areas undergoing stimulation, the potential for impacts on water resources, the process and chemicals used and the potential risks associated with chemicals and backflow water handled and stored above grade.

EHS Support, LLC (EHS Support) conducted a persistence, bioaccumulation and toxicity (PBT) assessment and and a Quantitative Risk Assessment (QRA) to meet Conditions 49e and 49f of the 2 October 2011 approval under the *Environmental Protection and Biodiversity Conservation Act 1999* (EPBC 2008/4059) and the Environmental Amendment (EA) conditions to assess the toxicity of the mixtures.

The results and conclusions of the qualitative risk assessment components and the QRA are presented below. Refer to **Section 6.0** through **Section 8.0** for detailed discussions on the methodologies employed for the qualitative risk assessment and QRA components, which are referenced in the sections below.

C2.0 Qualitative Risk Assessment and Evaluation

C2.1 Chemicals Evaluated

The Schlumberger Sapphire LF 'fluid system' was assessed. The list of individual chemicals is presented in **Table 1** below. A mass balance of the chemicals is provided as **Appendix C7-1**.

Information regarding the chemical and physical properties of the individual chemicals listed below can be found on the Saftey Data Sheets in **Appendix E**.

While none of the fracturing fluid chemicals identified contain benzene, toluene, ethylbenzene, xylenes (BTEX) or polycyclic aromatic hydrocarbons (PAHs), PAHs occur naturally in coal and it is possible that certain PAHs may naturally be present in the coal seam groundwater used in the hydraulic fracturing process.

Table 1: Hydraulic fracturing chemicals

Chemical	CAS Number
Crystalline silica	14808-60-7
Sodium carboxymethylcellulose	9004-32-4
2-hydroxy-N,N,N-trimethylethanaminium chloride (Choline chloride)	67-48-1

Magnesium chloride	7786-30-3
Magnesium silicate hydrate (talc)	14807-96-6
2-methyl-2h-isothiazol-3-one	2682-20-4
Vinylidene chloride/methylacrylate copolymer	25038-72-6

C2.2 Risk Assessment Framework and Findings

As discussed in **Section 5.0**, a systematic weight of evidence approach was utilised to complete the risk assessment for the Schlumberger fluid systems. The work has involved the following evaluations:

Qualitative Assessment Methodologies

- PBT Assessment
- Exposure Assessment
- Mass Balance of Fluid System
- Fate and Transport Modeling.

Quantitative Risk Assessment Methodologies

- Quantitative Human Health Risk Assessment (HHRA)
- Quantitative Ecological Risk Assessment for Terrestrial and Aquatic Receptors.

C2.3 PBT Assessment

The PBT approach outlined in **Section 6.1** was undertaken to rank the hydraulic fracturing chemicals based on persistence (P), bioaccumulation (B) and toxic (T) potential. As a result of this assessment,

no chemical constituents identified in the Sapphire LF fluid system were classified as a PBT chemical and are therefore not considered to be inherently hazardous. The results of the PBT Assessment are presented in **Table 2**, attached.

C2.4 Exposure Assessment

As discussed in **Section 7.0**, the exposure assessment identified receptors potentially exposed to chemicals of potential concern (COPC) identified for the study and outlines the exposure pathways by which the receptors may come in to contact with the COPCs. A detailed exposure assessment was not conducted in the qualitative risk assessment.

C2.5 Mass Balance of Fluid System

A quantitative mass balance calculation was undertaken to identify the amount of each chemical additive of the hydraulic fracturing fluid system. The results of the mass balance calculations are presented in **Appendix C7-1**.

C2.6 Fate and Transport Modelling

As discussed in **Section 7.2**, fate and transport modelling was conducted on a range of key constituents of interest in typical hydraulic fracturing fluid systems. These results provided the framework for assessing potential mobility of all constituents used in hydraulic fracturing. The modelling demonstrated that despite the variability in chemical properties between fluid systems there is limited potential for chemicals to migrate within the coal seams. Refer to **Section 7.2** for further detail.

C3.0 Quantitative Risk Assessment

In accordance with the methodologies presented in **Section 8.0**, a QRA was conducted on theoretical datasets for those chemicals identified in the Sapphire LF fluid system. The QRA approach evaluates the toxicity of the individual substances and characterises the cumulative risks of the total effluent toxicity and ecotoxicity.

Generally, this methodology includes the identification of the hazards posed by constituents in the flowback water, compilation of the toxicity criteria for each constituent, development of exposure models to estimate the daily intake of the constituents, and calculations of individual constituent hazard quotients (daily intake divided by the toxicity criteria) and a cumulative constituent hazard index (HI) for each potentially complete exposure pathway for each human or terrestrial receptor.

Potential complete exposure pathways to the storage of flowback from hydraulically stimulated wells and potential risks to humans, terrestrial and aquatic receptors from the potential storage and accidental releases are evaluated in the QRA.

No further assessment of groundwater was determined to be necessary due to lack of potentially complete exposure pathways. Detailed operational procedures have been provided that are designed to contain the hydraulic fracturing fluids within the coal sequences, and no connection exists between groundwater in the coal seams and surface-water or springs (and therefore Matters of National Environmental Significance [MNES]). Further, the potential risks to workers involved with the hydraulic fracturing process were not considered as detailed Health and Safety (H&S) procedures are employed to manage exposures. The QRA considered the following specific exposure pathways:

1. Exposure of trespassers to flowback water contained within flowback storage ponds.
2. Exposure of terrestrial receptors (e.g., livestock and wildlife) to flowback water contained within the flowback storage ponds.
3. Exposure of aquatic receptors to flowback water in the situation of an accidental release, such as from piping or a release from the flowback storage pond. These potential releases could include a failure of containment systems, overtopping of the dam or in an extreme situation (considered highly unlikely) structural failure of the dam itself.

C3.1 Exposure Assessment

The purpose of the exposure assessment in the QRA was to predict the magnitude and frequency of potential human exposure to each COPC following the methodologies presented in **Section 8.1**. A conceptual site model (CSM) was developed which describes the potential receptors and exposure scenarios for the flowback water used in this exposure assessment. The potential exposures to receptors were evaluated based on the potential for a complete exposure pathway.

As discussed in **Section 8.3**, exposure point concentrations (EPCs) were derived for the theoretical assessment; empirical data were not available for evaluation. The EPCs for the theoretical assessment were calculated by estimating the mass and discharge flow of the COPCs in the flowback water.

C3.2 Human Health QRA

A human health hazard assessment was conducted according to the methodologies presented in **Section 8.4**. The purpose of the hazard assessment process was to summarise the environmental data, and to address the toxicological assessment of the COPCs that will be evaluated further in the risk assessment process.

Exposure assumptions for the human trespasser scenario were developed based on default or site-specific assumptions (**Section 8.4**). This receptor exposure pathway includes a small child to teenager that may come in contact with the above grade water exposure scenario for approximately 20 days/year for a 10-year period with potential incidental ingestion (of 50 millilitres [ML] of water) and dermal contact (e.g., swimming where the whole body gets wet) for one half hour. The exposure parameters used in the QRA are presented on **Table 3**, attached.

Calculation of intake of COPCs was performed using the equations presented below:

Ingestion of water:

$$Intake\ (mg/kg-day)\ =\ (CW\ x\ IR\ X\ EF\ X\ ED)\ /\ (BW\ x\ AT)$$

Dermal contact with water:

$$Absorbed\ dose\ (mg/kg-day)\ =\ (CW\ x\ SA\ x\ DP\ x\ ET\ x\ EF\ x\ ED\ x\ CF)\ /\ (BW\ x\ AT)$$

Where:

CW = concentration in water (mg/l)
ET = exposure time (hr/day or hours/hours)
EF = exposure frequency (day/year)
ED = exposure duration (years)
CF = correction factor (1 x 10^{-3} l/cm^3)
AT = averaging time (days)
IR = ingestion rate (l/hr)
BW = body weight (kg)
SA = skin surface area available for contact (cm^2/d)
DP = dermal permeability factor (Kp – cm/hr).

C3.3 Toxicity Assessment

A toxicity assessment was conducted to determine the relationship between the dose of a COPC taken into the body, and the probability that an adverse effect will result from that dose. Quantitative estimates of the potency of COPCs include two sets of toxicity values, one for genotoxic carcinogens and one for other non-genotoxic carcinogens and non-carcinogenic effects. As discussed in **Section 8.4,** detailed toxicological profiles were developed for the chemicals. The toxicological profiles are included as **Appendix F**.

The assessment of toxicity of the COPCs was used to develop initial screening criteria for human health exposure scenarios as discussed in **Section 8.4**. The derivation of Oral Reference Dose and Drinking Water Guideline Values are presented in **Table 4**, attached, and the Australian Drinking Water Screening Values are presented in **Table 5**, attached.

C3.4 Exposure Point Concentration

As presented above, the exposure scenarios are based on anticipated conditions, and the potential for exposure to the theoretical estimate of exposure. EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations and the existing environmental conditions within the fracturing fluids sump or mud pit, and the flowback storage ponds.

For the theoretical calculations, the mass and estimated chemical concentrations of the COPCs in the Sapphire LF fluids, as presented in **Appendix C7-1**, were used to estimate the potential concentrations in water within the fracturing fluids sump or flare pit, or flowback storage ponds. Based on stimulation flow back monitoring conducted by Santos and the QRA completed for the Schlumberger Fluid Systems

(**Appendix C**), 20 percent (%) of the total mass of constituents injected is assumed to be recovered in the flowback water. This mass is diluted within 150 % of the injected volume (the minimum volume that must be flowed back) to establish an "estimated" concentration (i.e., concentration expected due to full dilution of the back flow water) within the flowback storage ponds.

The flowback water will be contained within the flowback storage ponds for a projected maximum period of one year of operational activity before transfer or conveyance to the water treatment facilities. Therefore, the concentration of COPCs in the flowback storage pond water was adjusted, where applicable, to account for the biodegradation and photolytic degradation of constituents over time. The biodegradation information was obtained from the Organisation for Economic Cooperation and Development (OECD) ready tests (OECD, 1992) that were developed as a first-tier testing scheme to provide preliminary screening of organic chemicals. The ready tests are stringent screening tests that are conducted under aerobic conditions in which a high concentration of the test substance is used, and biodegradation is measured by non-specific parameters including dissolved organic carbon, biochemical oxygen demand and carbon dioxide production. **Table 6**, attached, presents the environmental fate information that was used to assess biodegradation of COPCs, and that was applied at the time periods of 0, 30, 150 and 300 days from initial flowback.

The water quality data derived using these assumptions for the theoretical COPCs are presented in **Appendix C7-1**.

The theoretical EPCs for the four exposure time periods (0, 30, 150 and 300 days) were compared to human health toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Appendix C7-2**. There were no exceedance of the screening levels based either on an individual comparison, or on a cumulative comparison.

C3.5 Risk Estimation

Risk estimation was performed in accordance with the methodologies outlined in **Section 8.4**. The total target risk range for carcinogens was 1×10^{-4} to 1×10^{-6}; the target HI for non-threshold effects is less than or equal to 1.0.

No carcinogenic compounds are present in the stimulation fluids injected into the subsurface and as a result, only non-carcinogenic risks were calculated.

The results of the theoretical assessments for Sapphire LF fluid systems for the trespasser exposure scenarios (day 0 and day 150, Sapphire LF events) are summarized in **Tables 7** and **8**, attached. As discussed above, the theoretical assessment was only conducted at the well pad sites.

The exposure scenarios include the Sapphire LF fluid system event, as presented in **Appendix C7-1** for day 0 and day 150 from the flowback storage pond. The trespasser for day 0 did not have unacceptable risks for the Sapphire LF fluid system (HI=1.5×10^{-4}, **Table 7**, attached). The trespasser for day 150 did not have unacceptable risks for the Sapphire LF fluid system (HI=1.6×10^{-7}, **Table 8**, attached).

On this basis and using the theoretical concentrations, no adverse effects are predicted on trespassers.

C3.6 Ecological Risk Assessment

As discussed in **Section 8.5**, a screening level ecological risk assessment (ERA) was conducted to evaluate the potential for adverse ecological effects to terrestrial and aquatic ecological receptors that may be exposed to residual levels of hydraulic fracturing fluids in surface water used in the coal seam gas (CSG) fields.

C3.7 Exposure Assessment

Terrestrial receptors evaluated in the ERA include domesticated livestock, large mammalian wildlife and small mammalian wildlife. Beef cattle were used to evaluate domesticated livestock, kangaroos evaluated for large mammalian wildlife, and dingos for small mammalian wildlife. Aquatic receptors evaluated included invertebrates and fishes.

The estimate for dose-based or intake rates for the assessment endpoints for wildlife representing domestic livestock and native mammalian species used the following general equation:

$TI = C_{water} \times IR_{water} \times EF \times ED / BW \times ED \times 365$ days/year

Where:

TI = Total intake of COPC (mg/kg/day)
C_{water} = Concentration of COPC in water (mg/l)
IR_{water} = Ingestion rate (litres/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
BW = Body weight (kg).

The exposure assumptions are presented in **Tables 9** through **11**.

C3.8 Toxicity Assessment

To evaluate the potential for adverse ecological effects, toxicity reference values (TRVs) are selected as measurement endpoints for the ERA that will be used in the risk analysis. The TRVs are based on COPC levels that imply no adverse effects or levels that represent the lowest concentration at which adverse effects may occur. The ERA used two types of TRVs. The first TRV is a concentration-based TRV to evaluate the concentration of the selected COPC in the surface water and direct exposure by the aquatic ecological receptor. The determination of TRVs for freshwater was conducted according to the predicted no-effects concentration (PNEC) guidance in the Environmental Risk Assessment Guidance Manual for Industrial Chemicals prepared by the Australian Environmental Agency (AEA, 2009). As discussed in **Section 8.4**, detailed environmental profiles were developed for the chemicals. The environmental profiles are included in the risk dossiers in **Appendix G**. **Table 12**, attached, presents the COPC, the endpoint, NOEC [milligrams per litre (mg/L)], assessment factor and the aquatic PNEC (mg/L). The second TRV is a dose-based TRV to evaluate the intake dose of the selected COPC from exposure to surface water by ingestion. The calculated TRVs for each of the mammalian ecological receptors evaluated in the ERA are presented in the species-specific ecological risk models.

C3.9 Exposure Point Concentration

EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations. The potentially affected flowback water that represents complete exposure pathways for the ecological receptors includes the surface water systems (e.g., flowback storage ponds and mud pits) that were used to estimate the EPCs for the human health receptors. Similar to the EPCs for the human health receptors, the EPCs for the ecological receptors assumed 20 % of mass returned in the flowback water was diluted within 150 % of the injected volume of return water and was then adjusted based on biodegradation rates to calculate the theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days). **Appendix C7-1** presents the calculated EPCs for the ecological receptor exposure scenarios. The theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days) were compared to ecological based toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Appenidix C7-3**.

Risks were characterised in accordance with the methodologies discussed in **Section 8.5.5**. The resulting ecological hazard quotient must be less than or equal to 1.0 for risks to be considered acceptable.

C3.10 Estimation of Risk

The HI calculated for flowback water for aquatic risk were elevated above the acceptable level for less than half of COPCs evaluated (**Appendix C7-3**). Where large discharges of flowback water occur to surface water and/or flux dilution within the surface-water was insufficient, potential impacts on aquatic receptors could occur. As noted in the toxicity assessment section above, the lack of a robust aquatic toxicological database resulted in highly conservative aquatic screening values for the theoretical exposure scenario COPCs to be conservatively very low.

The results of the theoretical assessments for Sapphire LF fluid systems for the livestock cattle, kangaroo and dingo are summarized in **Tables 13** through **18**, attached. The exposure scenarios include the Sapphire LF fluid systems EPCs presented in **Appendix C7-1** for day 0 and day 150 from the fracturing fluid well flowback. The modelled risks from Sapphire LF fluid system chemicals in the flowback water were acceptable for the livestock cattle (HI=4.6 x 10^{-4} to 8.9 x 10^{-8}), **Table 13** and **14**, attached), kangaroo (HI= HI=9.4 x 10^{-5} to 1.8 x 10^{-8}), **Table 15** and **16**, attached), and dingo (HI=3.9 x 10^{-5} to 7.4 x 10^{-9}) for both exposure scenarios (**Tables 17** and **18**, attached).

C4.0 Summary of QRA Findings

The QRA was completed as discussed in **Section 8.0**. An assessment was conducted using highly conservative theoretical calculations based on the chemicals utilised by Schlumberger in hydraulic fracturing. This assessment assumed that a range of theoretical concentrations of injected chemicals would be present in the flowback water based on biodegradation rates, where applicable.

Consistent with the risk assessment and groundwater fate and transport modelling conducted by Golder, no potentially complete exposure pathways were identified for groundwater. Potential exposures are limited to the aboveground storage and handling of flowback water as part of the CSG Water Management Plan (WMP). Management of CSG water involves the temporary storage of flowback water in flowback storage ponds.

The results of the qualitative PBT Assessment indicated that no chemical constituents identified in the Sapphire LF fluid system was classified as a PBT chemical and therefore fluids containing these chemicals are not considered inherently hazardous.

The two exposure scenarios modelled for the QRA were 20 % flowback return, and either 0 or 150-day retention with EPC based on applicable degradation rates. Based on quantitative risk calculations, the potential risks to the trespasser associated with the flowback water are acceptable. There were no carcinogenic risks identified.

The modelled risks from Sapphire LF fluid system chemicals in the flowback water were acceptable for the livestock cattle, kangaroo, and dingo for both exposure scenarios.

Similarly, potential impacts could occur if releases of flowback water were to occur to aquatic environments. Based on the use of low permeability materials (clay liners) and operational controls that limit the potential for turkey nest and dam overflows, the potential for these risks are also considered limited.

A combination of management and operational controls are being implemented to eliminate and control the potential for exposures. These include:

- Worker training and hazard identification
- Use of appropriate personal protective equipment (gloves, etc.)
- Flowback storage pond fencing to prevent entry of livestock and native fauna and minimise trespassing
- Use of low permeability materials or dam liners and routine dam inspections to prevent releases from flowback storage ponds
- Routine operational and security patrols to prevent trespassing.

C5.0 Conclusions

A weight-of-evidence evaluation of potential risks as described in **Section 5.0** was performed for the Schlumberger Sapphire LF fluid system. Based on the qualitative and quantitative risk characterisations, the overall risk to human health and the environment is low. Existing operational control activities employed by Santos are in place that will limit the potential risks to human health and the environment. These measures include:

- Occupational health and safety procedures implemented during hydraulic fracturing operations to prevent workers from direct contact with chemicals during spills and when handling flowback water or sediments;
- Environmental authority conditions that preclude the construction of well pads within 100 metres of a watercourse of water body;
- Implementation of spill containment procedures during operations to prevent migration of and exposure to chemicals;
- Disposal or capping of sediments contained within drained mud pits and turkey nests, to prevent exposure to contaminates in windborne dust;
- Fencing of drill pads to prevent trespassers and installation of signs to indicate that the water in the turkeys nest and mud pit is not potable and may contain contaminants;
- Installation and maintenance of fences around the well pad to prevent access to the drill pad by livestock and large native fauna;
- Santos operational procedures to ensure well integrity and design of fracture to stay within the target seam; and
- Mud pits and turkeys nests with clay liners, or similar material, to prevent seepage of flowback water into underlying aquifers.

Regular monitoring of water supply bores and surface water for a representative suite of chemicals within 2 kilometre of wells (and 200 m vertical separation) that are fractured is required to confirm the conclusion of incomplete exposure pathways and low risk.

No additional risks, other than those previously discussed, were identified with the chemicals or systems employed by Schlumberger in hydraulic fracturing. Evaluation of other potential risks associated with hydraulic fracturing (i.e., noise and vibration) was conducted. Refer to **Section 9.0** for methodology specifics and results of this evaluation.

Tables

Table 2. PBT Assessment of the Sapphire LF Fluid System

Substance	P/vP criteria fulfilled?	B/vB criteria fulfilled?	T criteria fulfilled?	Overall Conclusion
Sodium carboxymethylcellulose (9004-32-4)	Yes (water-soluble polymer)	No (polymer; not bioavailable)	No (polymer; not bioavailable)	Not PBT (based on physico-chemical properties)
2-hydroxy-N,N,N-trimethylethanaminium chloride (Choline chloride) (67-48-1)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
2,2′,2″-nitrilotriethanol (102-71-6)	No (screening data available)	No (experimental data available)	No (experimental data available)	Not PBT (based on screening and experimental data)
Diammonium peroxidisulphate (7727-54-0)	Not applicable (ionic species ubiquitous in environment)	No (essential ions to biological systems; actively regulated)	No (screening data available)	Not PBT (based on screening data and ubiquitous inorganic salt)
Vinylidene chloride/methylacrylate copolymer (25038-72-6)	Yes (polymer not biodegradable)	No (polymer; not bioavailable)	No (polymer; not bioavailable)	Not PBT
Diatomaceous earth, calcined (91053-39-3)	Yes (naturally-occurring inorganic mineral)	No (water-insoluble mineral; not bioavailable)	No (water-insoluble mineral; not bioavailable)	Not PBT (based on physico-chemical properties)
Magnesium nitrate (10377-60-3)	Not applicable (ionic species ubiquitous in environment)	No (Mg is an essential ion to biological systems; nitrate ions are water-soluble)	No (screening data available)	Not PBT (based on screening data and ubiquitous inorganic salt)
5-chloro-2-methyl-2h-isothazolo-3-one/2-methyl-2h-isothiasol-3-one [3:1] (55965-84-9)	No (experimental data available)	No (experimental data available)	Yes (screening data available)	Not PBT (based on screening and experimental data)

Table 2. PBT Assessment of the Sapphire LF Fluid System

Substance	P/vP criteria fulfilled?	B/vB criteria fulfilled?	T criteria fulfilled?	Overall Conclusion
Magnesium silicate hydrate [talc] (14807-96-6)	Yes (naturally-occurring inorganic mineral)	No (water-insoluble mineral; not bioavailable)	No (water-insoluble mineral; not bioavailable)	Not PBT (based on physico-chemical properties)
Magnesium chloride (7786-30-3)	Not applicable (ionic species ubiquitous in environment)	No (essential ions to biological systems; actively regulated)	No (screening data available)	Not PBT (based on screening data and ubiquitous inorganic salt)
Cristobalite (14464-46-1)	Yes (naturally-occurring inorganic mineral)	No (water-insoluble mineral; not bioavailable)	No (water-insoluble mineral; not bioavailable)	Not PBT (based on physico-chemical properties)
Crystalline Silica (14808-60-7)	Yes (naturally-occurring inorganic mineral)	No (water-insoluble mineral; not bioavailable)	No (water-insoluble mineral; not bioavailable)	Not PBT (based on physico-chemical properties)

Santos

Appendix C8
Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3

C1.0 Introduction

Santos Ltd. (Santos) is looking to use a borate, guar-based crosslinked Halliburton hydraulic fracturing fluid system (the fluid system) for development of coal seam gas (CSG) resources in the Surat and Bowen Basins of Queensland, specifically in the Roma Shallow Gas Project Area (RSGPA). The disclosure for well RM08-14-3, including a listing of the chemical constituents and percent (%) of total volume in the fluid system, is provided in **Appendix C8-1**. The fluid system components provided in **Appendix C8-1** were addressed previously as part of the Hydraulic Fracturing Risk Assessment by Santos (2021), with the exception of the following:

- Hydoxylpropyl guar
- Ulexite
- Disodium octaborate tetrahydrate.

Specifically, the assessed fluid system components were addressed either in the Delta 140 fluid system (Appendix C2 and C5), the Clean Stim fluid system (Appendix C3), or the Y120 Flex fluid system (Appendix C6).

As presented in **Section 5.0**, Santos used a weight-of-evidence approach to evaluate the potential for human health and environmental (e.g., ecological) risks as a result of the hydraulic fracturing processes and the use of the Halliburton Hydraulic Fracturing Fluid System in Well RM 08-14-3.

EHS Support, LLC (EHS Support) conducted a Quantitative Risk Assessment (QRA) to meet Conditions 49e and 49f of the 2 October 2011 approval under the *Environmental Protection and Biodiversity Conservation Act 1999* (EPBC 2008/4059) and the Environmental Amendment (EA) conditions to assess the toxicity of the mixtures.

The results and conclusions of the qualitative risk assessment components and the QRA are presented below. Refer to **Section 6.0** through **Section 8.0** for detailed discussions on the methodologies employed for the qualitative risk assessment and QRA components, which are referenced in the sections below.

C2.0 Qualitative Risk Assessment and Evaluation

C2.1 Chemicals Evaluated

The Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 was assessed. The list of individual chemicals is presented in **Table 1** below. A mass balance of the chemicals is provided as **Table C8-1**.

Information regarding the chemical and physical properties of the individual chemicals listed can be found on the Safety Data Sheets in **Appendix E**.

The fluid system does not contain BTEX (benzene, toluene, ethylbenzene, xylenes) or polycyclic aromatic hydrocarbons (PAHs) based on EHS Support's understanding that Halliburton has tested all of their products. Field monitoring will also be conducted in accordance with regulatory requirements. While none of the fracturing fluid chemicals identified contain BTEX or PAHs, PAHs occur naturally in coal and it is possible that certain PAHs may naturally be present in the coal seam groundwater used in the hydraulic fracturing process.

Table 1: Hydraulic fracturing chemicals

Chemical	CAS Number
Hydroxypropyl guar	39421-75-5
Triethanolamine	107-71-6
Monoethanolamine borate	26038-87-9
Ulexite	1319-33-1
Ethylene glycol	107-21-1
Diethanolamine	111-42-2
Acetic acid	64-19-2
Sodium hydroxide	1310-73-2
Lactose	63-42-3
Disodium octaborate tetrahydrate	12280-03-4
Crystalline Silica	14808-60-7
Tributyl tetradecyl phosphonium chloride	81741-28-8
Silica dioxide	7631-86-9
Sodium carbonate	497-19-8
Hemicellulase enzyme	9012-54-8

C2.2 Risk Assessment Framework and Findings

As discussed in **Section 5.0**, a systematic weight of evidence approach was utilised to complete the risk assessment for the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3. The work has involved the following evaluations:

Qualitative Assessment Methodologies

- PBT Assessment
- Exposure Assessment
- Mass Balance of Fluid System
- Fate and Transport Modeling.

Quantitative Risk Assessment Methodologies

- Quantitative Human Health Risk Assessment (HHRA)
- Quantitative Ecological Risk Assessment for Terrestrial and Aquatic Receptors.

C2.3 PBT Assessment

For the environmental hazard assessment, a PBT (persistence, bioaccumulative, toxicity) assessment was conducted in accordance with the guidance developed by DEWHA (2009), as presented in **Section 6.1**. The PBT assessment is conducted because of specific concerns for substances that can be shown to persist for long periods in the environment, to bioaccumulate in food chains, and can give rise to toxic effects after a longer time and over a greater spatial scale than chemicals without these properties. These effects may be difficult to detect at an early stage because of long-term exposures at normally low concentration levels and long life-cycles of species at the top of the food chain.

The PBT approach outlined in **Section 6.1** was undertaken to rank the hydraulic fracturing chemicals based on PBT potential. As a result of this assessment, no chemical constituents identified in the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 were classified as a PBT chemical and are therefore not considered to be inherently hazardous (**Appendix G**). The results of the PBT Assessment are presented in **Table 2**, attached.

C2.3 Exposure Assessment

As discussed in **Section 7.0**, the exposure assessment identified receptors potentially exposed to chemicals of potential concern (COPC) identified for the study and outlines the exposure pathways by which the receptors may come in to contact with the COPCs. A detailed exposure assessment was not conducted in the qualitative risk assessment.

C2.4 Mass Balance of Fluid System

A quantitative mass balance calculation was undertaken to identify the amount of each chemical additive of the hydraulic fracturing fluid system. The results of the mass balance calculations are presented in **Table C8-1**.

C2.5 Fate and Transport Modelling

As discussed in **Section 7.2**, fate and transport modelling was conducted on a range of key constituents of interest in typical hydraulic fracturing fluid systems. These results provided the framework for assessing potential mobility of all constituents used in hydraulic fracturing. The modelling demonstrated that despite the variability in chemical properties between fluid systems there is limited potential for chemicals to migrate within the coal seams. Refer to **Section 7.2** for further detail.

C3.0 Quantitative Risk Assessment

In accordance with the methodologies presented in **Section 8.0**, a QRA was conducted on theoretical datasets for those chemicals identified in the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3. The QRA approach evaluates the toxicity of the individual substances and characterises the cumulative risks of the total effluent toxicity and ecotoxicity.

Generally, this methodology includes the identification of the hazards posed by constituents in the flowback water, compilation of the toxicity criteria for each constituent, development of exposure models to estimate the daily intake of the constituents, and calculations of individual constituent hazard quotients (daily intake divided by the toxicity criteria) and a cumulative constituent hazard index (HI) for each potentially complete exposure pathway for each human or terrestrial receptor.

Potential complete exposure pathways to the storage of flowback from hydraulically stimulated wells, and potential risks to humans, terrestrial and aquatic receptors from the potential storage and accidental releases are evaluated in the QRA.

No further assessment of groundwater was determined to be necessary due to lack of potentially complete exposure pathways. Detailed operational procedures have been provided that are designed to contain the hydraulic fracturing fluids within the coal sequences, and no connection exists between groundwater in the coal seams and surface-water or springs (and therefore Matters of National Environmental Significance [MNES]). Further, the potential risks to workers involved with the hydraulic fracturing process were not considered as detailed Health and Safety (H&S) procedures are employed to manage exposures. The QRA considered the following specific exposure pathways:

1. Exposure of trespassers to flowback water contained within flowback storage ponds.
2. Exposure of terrestrial receptors (e.g., livestock and wildlife) to flowback water contained within the flowback storage tank.
3. Exposure of aquatic receptors to flowback water in the situation of an accidental release, such as from piping or a release from the flowback storage tank. These potential releases could include a failure of containment systems, overtopping of the dam or in an extreme situation (considered highly unlikely) structural failure of the dam itself.

C3.1 Exposure Assessment

The purpose of the exposure assessment in the QRA was to predict the magnitude and frequency of potential human exposure to each COPC following the methodologies presented in **Section 8.1**. A conceptual site model (CSM) was developed which describes the potential receptors and exposure scenarios for the flowback water used in this exposure assessment. The potential exposures to receptors were evaluated based on the potential for a complete exposure pathway.

As discussed in **Section 8.3**, exposure point concentrations (EPCs) were derived for the theoretical assessment; empirical data were not available for evaluation. The EPCs for the theoretical assessment were calculated by estimating the mass and discharge flow of the COPCs in the flowback water.

C3.2 Human Health QRA

A human health hazard assessment was conducted according to the methodologies presented in **Section 8.4**. The purpose of the hazard assessment process was to summarise the environmental data, and to address the toxicological assessment of the COPCs that will be evaluated further in the risk assessment process.

Exposure assumptions for the human trespasser scenario were developed based on default or site-specific assumptions (**Section 8.4**). This receptor exposure pathway includes a small child to teenager

that may come in contact with the above grade water exposure scenario for approximately 20 days/year for a 10-year period with potential incidental ingestion [of 50 millilitres (ML) of water] and dermal contact (e.g., swimming where the whole body gets wet) for one half hour. The exposure parameters used in the QRA are presented on **Table 3**, attached.

Calculation of intake of COPCs was performed using the equations presented below:

Ingestion of water:

$$Intake\ (mg/kg-day)\ =\ (CW\ x\ IR\ X\ EF\ X\ ED)\ /\ (BW\ x\ AT)$$

Dermal contact with water:

$$Absorbed\ dose\ (mg/kg-day)\ =\ (CW\ x\ SA\ x\ DP\ x\ ET\ x\ EF\ x\ ED\ x\ CF)\ /\ (BW\ x\ AT)$$

Where:

CW = concentration in water (mg/l)
ET = exposure time (hr/day or hours/hours)
EF = exposure frequency (day/year)
ED = exposure duration (years)
CF = correction factor (1 x 10-3 l/cm3)
AT = averaging time (days)
IR = ingestion rate (l/hr)
BW = body weight (kg)
SA = skin surface area available for contact (cm2/d)
DP = dermal permeability factor (Kp – cm/hr).

C3.3 Toxicity Assessment

A toxicity assessment was conducted to determine the relationship between the dose of a COPC taken into the body, and the probability that an adverse effect will result from that dose. Quantitative estimates of the potency of COPCs include two sets of toxicity values, one for genotoxic carcinogens and one for other non-genotoxic carcinogens and non-carcinogenic effects. As discussed in **Section 8.4**, detailed toxicological profiles were developed for the chemicals. The toxicological profiles are included as **Appendix F8**.

The assessment of toxicity of the COPCs was used to develop initial screening criteria for human health exposure scenarios as discussed in **Section 8.4**. The derivation of Oral Reference Dose and Drinking Water Guideline Values are presented in **Table 4**, attached.

C3.4 Exposure Point Concentration

As presented above, the exposure scenarios are based on anticipated conditions, and the potential for exposure to the theoretical estimate of exposure. EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations and the existing environmental conditions within the fracturing fluids flowback storage ponds, and the flowback used in the irrigation fields.

To assess the potential flux of hydraulic fracturing chemicals to the environment, vendor disclosures for the hydraulic fracturing fluid systems were reviewed, and the chemical concentrations of key inputs were determined. It should also be noted that diethanolamine is a new chemical, and is only included as a contingency; at this time it is unlikely to be used.

For the theoretical calculations, the mass and estimated chemical concentrations of the COPCs in the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3, as presented in **Table C8-1**, were used to estimate the potential concentrations in water within the fracturing fluids sump or flare pit, or

flowback storage ponds. Based on stimulation flow back monitoring conducted by Santos and the QRA completed for the Schlumberger Fluid Systems (**Appendix C**), 20 % of the total mass of constituents injected is assumed to be recovered in the flowback water. This mass is diluted within 150 % of the injected volume (the minimum volume that must be flowed back) to establish an "estimated" concentration (i.e., concentration expected due to full dilution of the back flow water) within the flowback storage ponds.

The flowback water will be contained within the flowback storage ponds for a projected maximum period of one year of operational activity before transfer or conveyance to the water treatment facilities and or transferred into Santos water convenyance systems (for treatment) and thereby blended with other coal seam gas (CSG) water not containing these constituents. To be conservative it has been assumed that the fluids are stored with ponds with theconcentration of COPCs in the flowback storage pond water adjusted, where applicable, to account for the biodegradation and photolytic degradation of constituents over time. The biodegradation information was obtained from the Organisation for Economic Cooperation and Development (OECD) ready tests (OECD, 1992) that were developed as a first-tier testing scheme to provide preliminary screening of organic chemicals. The ready tests are stringent screening tests that are conducted under aerobic conditions in which a high concentration of the test substance is used, and biodegradation is measured by non-specific parameters including dissolved organic carbon, biochemical oxygen demand and carbon dioxide production. **Table 6**, attached, presents the environmental fate information that was used to assess biodegradation of COPCs, and that was applied at the time periods of 0, 30, 150 and 300 days from initial flowback.

The water quality data derived using these assumptions for the theoretical COPCs are presented in **Table C8-1**.

The theoretical EPCs for the four exposure time periods (0, 30, 150 and 300 days) were compared to human health toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C8-2**.

C3.5 Risk Estimation

Risk estimation was performed in accordance with the methodologies outlined in **Section 8.4**. The total target risk range for carcinogens was 1×10^{-4} to 1×10^{-6}; the target HI for non-threshold effects is less than or equal to 1.0.

Diethanolamine is the only carcinogenic compound present in the stimulation fluids injected into the subsurface. The toxicity criteria corresponding to an oral reference dose (**Table 4**, attached) was derived based on a cancer slope factor based on the NOAEL (See diethanolamine in **Appendix F8**).

The results of the theoretical assessments for Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 for the trespasser exposure scenarios (day 0 and day 150, Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 events) are summarized in **Tables 7** and **8**, attached. As discussed above, the theoretical assessment was only conducted at the well pad sites.

The exposure scenarios include the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 event, as presented in **Table C8-1**for day 0 and day 150 from the flowback storage tank. The trespasser for day 0 had no unacceptable risks for the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 (HI=0.088, **Table 7**, attached), and for day 150 (HI=0.065, **Table 8**, attached). There were no unacceptable risks for either day scenario.

On this basis and using the theoretical concentrations, on this basis and using the theoretical concentrations, no adverse effects are predicted on trespassers.

C3.6 Ecological Risk Assessment

As discussed in Section 8.5, a screening level ecological risk assessment (ERA) was conducted to evaluate the potential for adverse ecological effects to terrestrial and aquatic ecological receptors that may be exposed to residual levels of hydraulic fracturing fluids in surface water used in the CSG fields.

C3.7 Exposure Assessment

Terrestrial receptors evaluated in the ERA include domesticated livestock, large mammalian wildlife and small mammalian wildlife. Beef cattle were used to evaluate domesticated livestock, kangaroos evaluated for large mammalian wildlife, and dingos for small mammalian wildlife. Aquatic receptors evaluated included invertebrates and fishes.

The estimate for dose-based or intake rates for the assessment endpoints for wildlife representing domestic livestock and native mammalian species used the following general equation:

TI = Cwater x IRwater x EF x ED / BW x ED x 365 days/year

Where:

TI = Total intake of COPC (mg/kg/day)
Cwater = Concentration of COPC in water (mg/l)
IRwater = Ingestion rate (litres/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
BW = Body weight (kg).

The exposure assumptions are presented in **Tables 9** through **11**.

C3.8 Toxicity Assessment

To evaluate the potential for adverse ecological effects, toxicity reference values (TRVs) are selected as measurement endpoints for the ERA that will be used in the risk analysis. The TRVs are based on COPC levels that imply no adverse effects or levels that represent the lowest concentration at which adverse effects may occur. The ERA used two types of TRVs (**Section 8.5.3**). The first TRV is a concentration-based TRV to evaluate the concentration of the selected COPC in the surface water and direct exposure by the aquatic ecological receptor. The determination of TRVs for freshwater was conducted according to the predicted no-effects concentration (PNEC) guidance in the Environmental Risk Assessment Guidance Manual for Industrial Chemicals prepared by the Australian Environmental Agency (AEA, 2009). As discussed in **Section 8.4**, detailed environmental profiles were developed for the chemicals. The environmental profiles are included in the risk dossiers in **Appendix G**. **Table 12**, attached, presents the COPC, the endpoint, NOEC [milligrams per litre (mg/L)], assessment factor, and the aquatic PNEC (mg/L). The second TRV is a dose-based TRV to evaluate the intake dose of the selected COPC from exposure to surface water by ingestion. The calculated TRVs for each of the mammalian ecological receptors evaluated in the ERA are presented in the species-specific ecological risk models.

C3.9 Exposure Point Concentration

EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations. The potentially affected flowback water that represents complete exposure pathways for the ecological receptors includes the surface water systems (e.g., flowback storage ponds and mud pits) that were used to estimate the EPCs for the human health receptors. The EPCs for the ecological receptors were estimated assuming the same Scenarios, with exposure occurring in the

irrigation area where irrigation water may pool and wildlife may drink from the standing water. **Table C8-1**presents the calculated EPCs for the ecological receptor exposure scenarios. The theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days) were compared to ecological based toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C8-3**.

Risks were characterised in accordance with the methodologies discussed in **Section 8.5.6**. The resulting ecological hazard quotient must be less than or equal to 1.0 for risks to be considered acceptable.

C3.10 Estimation of Risk

The HI calculated for flowback water for aquatic risk were elevated above the acceptable level for the majority of COPCs evaluated (**Table C8-3**). Where large discharges of flowback water occur to surface water and/or flux dilution within the surface-water was insufficient, potential impacts on aquatic receptors could occur. As noted in the toxicity assessment section above, the lack of a robust aquatic toxicological database resulted in highly conservative aquatic screening values for the theoretical exposure scenario COPCs to be conservatively very low.

The results of the theoretical assessments for Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 for the livestock cattle, kangaroo and dingo are summarized in **Tables 13** through **18**, attached. The exposure scenarios include the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 EPCs presented in **Table C8-1** for day 0 and day 150 from the fracturing fluid well flowback. The modelled risks from Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 chemicals in the flowback water were acceptable for the livestock (HI=0.9 to 0.65, **Table 13** and **14**, attached), kangaroo (HI=0.18 0.13, **Table 15** and **16**, attached), and dingo (HI=0.075 to 0.054, **Table 17** and **18**, attached), for all exposure scenarios.

C4.0 Summary of QRA Findings

The QRA was completed as discussed in **Section 8.0**. An assessment was conducted using highly conservative theoretical calculations based on the chemicals utilised by Schlumberger in hydraulic fracturing. This assessment assumed that a range of theoretical concentrations of injected chemicals would be present in the flowback water based on biodegradation rates, where applicable.

Consistent with the risk assessment and groundwater fate and transport modelling conducted by Golder, no potentially complete exposure pathways were identified for groundwater. Potential exposures are limited to the aboveground storage and handling of flowback water as part of the CSG Water Management Plan (WMP). Management of CSG water involves the temporary storage of flowback water in flowback storage ponds.

The exposure scenario modelled for the QRA was a trespasser being exposed to flowback water under various EPC scenarios. Based on quantitative risk calculations, the potential risks for the trespasser were acceptable for the EPC scenarios. There were no carcinogenic risks identified.

The modelled risks from Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3 chemicals in the flowback water were acceptable for the livestock cattle, kangaroo, and dingo for all EPC exposure scenarios.

Similarly, potential impacts could occur if releases of flowback water were to occur to aquatic environments. Based on the use of low permeability materials (clay liners) and operational controls that limit the potential for turkey nest and dam overflows, the potential for these risks are also considered limited.

A combination of management and operational controls are being implemented to eliminate and control the potential for exposures. These include:

- Worker training and hazard identification
- Use of appropriate personal protective equipment (gloves, etc.)
- Flowback storage pond fencing to prevent entry of livestock and native fauna and minimise trespassing
- Use of low permeability materials or dam liners and routine dam inspections to prevent releases from flowback storage ponds
- Routine operational and security patrols to prevent trespassing.

C5.0 Conclusions

A weight-of-evidence evaluation of potential risks as described in Section 5.0 of the RA Compendium was performed for the Halliburton Hydraulic Fracturing Fluid System – Well RM 08-14-3. Based on the qualitative and quantitative risk characterisations, the overall risk to human health and the environment is acceptable. Existing operational control activities employed by Santos are in place that will limit the potential risks to human health and the environment. These measures include:

- Occupational health and safety procedures implemented during hydraulic fracturing operations to prevent workers from direct contact with chemicals during spills and when handling flowback water or sediments;
- Environmental authority conditions that preclude the construction of well pads within 100 metres of a watercourse of water body;
- Implementation of spill containment procedures during operations to prevent migration of and exposure to chemicals;
- Disposal or capping of sediments contained within drained mud pits and turkey nests , to prevent exposure to contaminates in windborne dust;
- Fencing of drill pads to prevent trespassers and installation of signs to indicate that the water in the turkeys nest and mud pit is not potable and may contain contaminants;
- Installation and maintenance of fences around the well pad to prevent access to the drill pad by livestock and large native fauna;
- Santos operational procedures to ensure well integrity and design of fracture to stay within the target seam; and
- Mud pits and turkeys nests with clay liners, or similar material, to prevent seepage of flowback water into underlying aquifers.

Monitoring of water supply bores and surface water for a representative suite of chemicals within 2 kilometre of wells (and 200 m vertical separation) that are fractured will be conducted (as needed) to confirm the conclusion of incomplete exposure pathways and low risk.

No additional risks, other than those previously discussed, were identified with the chemicals or systems employed in hydraulic fracturing. Evaluation of other potential risks associated with hydraulic fracturing (i.e., noise and vibration) was conducted. Refer to **Section 9.0** for methodology specifics and results of this evaluation.

Tables

Table 2: PBT Assessment of the Halliburton RM08-14-3 Fluid System

Substance	P/vP criteria fulfilled?	B/vB criteria fulfilled?	T criteria fulfilled?	Overall conclusion
Hydroxypropyl guar (39421-75-5)	No (screening data estimated)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Triethanolamine (107-71-6)	No (screening data available)	No (experimental data available)	No (experimental data available)	Not PBT (based on screening and experimental data)
Monoethanolamine borate (26038-87-9)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Ulexite (1319-33-1)	Yes (inorganic salt)	No (screening data available)	Yes (measured data; human health concerns)	Not PBT (based on screening and measured data)
Ethylene glycol (107-21-1)	No (screening data available)	No (measured data available)	No (measured data available)	Not PBT (based on screening and measured data)
Diethanolamine (111-42-2)	No (screening data available)	No (screening data available)	Human health concerns	Not PBT (based on screening and measured data)
Acetic acid (64-19-2)	No (screening data available)	No (screening data available)	No (measured data available)	Not PBT (based on screening and measured data)
Sodium hydroxide (1310-73-2)	Not applicable (ionic species ubiquitous in environment)	No (essential ions to biological systems; actively regulated)	No (screening data available)	Not PBT (based screening data and ubiquitous inorganic salt)
Lactose (63-42-3)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Disodium octaborate tetrahydrate (12280-03-4)	Yes (inorganic salt)	No (screening data available)	Yes (measured data; human health concerns)	Not PBT (based on screening and measured data)
Crystalline Silica (14808-60-7)	Yes (naturally-occurring inorganic mineral)	No (water-insoluble mineral; not bioavailable)	No (water-insoluble mineral; not bioavailable)	Not PBT (based on physico-chemical properties)
Tributyl tetradecyl phosphonium chloride (81741-28-8)	Yes (measured data available)	No (screening data available)	Yes (screening data available)	Not PBT (based on measured and screening data)
Silica dioxide	Yes (naturally-occurring inorganic mineral)	No (water-insoluble mineral; not bioavailable)	No (screening data available)	Not PBT (based on screening data and physic-chemical properties)
Sodium carbonate (497-19-8)	Not applicable (ionic species ubiquitous in environment)	No (essential ions to biological systems; actively regulated)	No (screening data available)	Not PBT (based screening data and ubiquitous inorganic salt)
Hemicellulase enzyme (9012-54-8)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)

Table 3 Exposure Assumptions - Trespasser

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/hr	0.05

Santos

Appendix C9
Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System

C1.0 Introduction

Santos Ltd. (Santos) is looking to use a water based (not gel based) Halliburton hydraulic fracturing fluid system (the fluid system) for development of coal seam gas (CSG) resources in the Surat and Bowen Basins of Queensland, specifically in the Roma Shallow Gas Project Area (RSGPA). The disclosure for well Mt Kingsley 6, including a listing of the chemical constituents and percent of total volume in the fluid system, is provided in **Appendix C9-1**. The fluid system components provided in **Appendix C9-1** comprises only three chemicals: BE-9 Algaecide (a biocide containing tributyl tetradecyl phosphonium chloride); Fluorescein Dye (sodium fluorescein); and potassium chloride (KCl) for clay inhibition. The anticipated chemical composition of the hydraulic fracturing fluid will comprise the following:

- Water 300,000 gallons
- KCl 100,200 pounds
- BE-9 180 gallons
- Flourescein Dye 5 pounds

As presented in **Section 5.0**, Santos used a weight-of-evidence approach to evaluate the potential for human health and environmental (e.g., ecological) risks as a result of the hydraulic fracturing processes and the use of the Halliburton Hydraulic Fracturing Fluid System in well Mt Kingsley 6.

EHS Support, LLC (EHS Support) conducted a Quantitative Risk Assessment (QRA) to meet Conditions 49e and 49f of the 2 October 2011 approval under the *Environmental Protection and Biodiversity Conservation Act 1999* (EPBC 2008/4059) and the Environmental Amendment (EA) conditions to assess the toxicity of the mixtures.

The results and conclusions of the qualitative risk assessment components and the QRA are presented below. Refer to **Section 6.0** through **Section 8.0** for detailed discussions on the methodologies employed for the qualitative risk assessment and QRA components, which are referenced in the sections below.

C2.0 Qualitative Risk Assessment and Evaluation

C2.1 Chemicals Evaluated

The Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System was assessed. The list of individual chemicals is presented in **Table 1** below. A mass balance of the chemicals is provided as **Table C9-1**.

Information regarding the chemical and physical properties of the individual chemicals listed below as well as the approximate percentage present in the hydraulic fracturing system can be found on the Safety Data Sheets in **Appendix E**.

The fluid system does not contain BTEX (benzene, toluene, ethylbenzene, xylenes) or polycyclic aromatic hydrocarbons (PAHs) based on EHS Support's understanding that Halliburton has tested all of their products. Field monitoring will also be conducted in accordance with regulatory requirements. While none of the fracturing fluid chemicals identified contain BTEX or PAHs, PAHs occur naturally in coal and it is possible that certain PAHs may naturally be present in the coal seam groundwater used in the hydraulic fracturing process.

Table 1: Hydraulic fracturing chemicals

Chemical	CAS Number
Sodium fluorescein	518-47-8
Tributyl tetradecyl phosphonium chloride	81741-28-8
Potassium chloride	7447-40-7

C2.2 Risk Assessment Framework and Findings

As discussed in **Section 5.0**, a systematic weight of evidence approach was utilised to complete the risk assessment for the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System. The work has involved the following evaluations:

Qualitative Assessment Methodologies

- PBT Assessment
- Exposure Assessment
- Mass Balance of Fluid System
- Fate and Transport Modeling.

Quantitative Risk Assessment Methodologies

- Quantitative Human Health Risk Assessment (HHRA)
- Quantitative Ecological Risk Assessment for Terrestrial and Aquatic Receptors.

C2.3 PBT Assessment

For the environmental hazard assessment, a PBT (persistence, bioaccumulative, toxicity) assessment was conducted in accordance with the guidance developed by DEWHA (2009), as presented in **Section 6.1**. The PBT assessment is conducted because of specific concerns for substances that can be shown to persist for long periods in the environment, to bioaccumulate in food chains, and can give rise to toxic effects after a longer time and over a greater spatial scale than chemicals without these properties. These effects may be difficult to detect at an early stage because of long-term exposures at normally low concentration levels and long life-cycles of species at the top of the food chain.

The PBT approach outlined in **Section 6.1** was undertaken to rank the hydraulic fracturing chemicals based on PBT potential. As a result of this assessment, no chemical constituents identified in the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System were classified as a PBT chemical and are therefore not considered to be inherently hazardous (**Appendix G**). The results of the PBT Assessment are presented in **Table 2**, attached.

C2.3 Exposure Assessment

As discussed in **Section 7.0**, the exposure assessment identified receptors potentially exposed to chemicals of potential concern (COPC) identified for the study and outlines the exposure pathways by which the receptors may come in to contact with the COPCs. A detailed exposure assessment was not conducted in the qualitative risk assessment.

C2.4 Mass Balance of Fluid System

A quantitative mass balance calculation was undertaken to identify the amount of each chemical additive of the hydraulic fracturing fluid system. The results of the mass balance calculations are presented in **Table C9-1**.

C2.5 Fate and Transport Modelling

As discussed in **Section 7.2**, fate and transport modelling was conducted on a range of key constituents of interest in typical hydraulic fracturing fluid systems. These results provided the framework for assessing potential mobility of all constituents used in hydraulic fracturing. The modelling demonstrated that despite the variability in chemical properties between fluid systems there is limited potential for chemicals to migrate within the coal seams. Refer to **Section 7.2** for further detail.

C3.0 Quantitative Risk Assessment

In accordance with the methodologies presented in **Section 8.0**, a QRA was conducted on theoretical datasets for those chemicals identified in the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System. The QRA approach evaluates the toxicity of the individual substances, and characterises the cumulative risks of the total effluent toxicity and ecotoxicity.

Generally, this methodology includes the identification of the hazards posed by constituents in the flowback water, compilation of the toxicity criteria for each constituent, development of exposure models to estimate the daily intake of the constituents, and calculations of individual constituent hazard quotients (daily intake divided by the toxicity criteria) and a cumulative constituent hazard index (HI) for each potentially complete exposure pathway for each human or terrestrial receptor.

Potential complete exposure pathways to the storage of flowback from hydraulically stimulated wells, and potential risks to humans, terrestrial and aquatic receptors from the potential storage and accidental releases are evaluated in the QRA.

No further assessment of groundwater was determined to be necessary due to lack of potentially complete exposure pathways. Detailed operational procedures have been provided that are designed to contain the hydraulic fracturing fluids within the coal sequences, and no connection exists between groundwater in the coal seams and surface-water or springs (and therefore Matters of National Environmental Significance [MNES]). Further, the potential risks to workers involved with the hydraulic fracturing process were not considered as detailed Health and Safety (H&S) procedures are employed to manage exposures. The QRA considered the following specific exposure pathways:

1. Exposure of trespassers to flowback water contained within flowback storage ponds.
2. Exposure of terrestrial receptors (e.g., livestock and wildlife) to flowback water contained within the flowback storage tank.
3. Exposure of aquatic receptors to flowback water in the situation of an accidental release, such as from piping or a release from the flowback storage tank. These potential releases could include a failure of containment systems, overtopping of the dam or in an extreme situation (considered highly unlikely) structural failure of the dam itself.

C3.1 Exposure Assessment

The purpose of the exposure assessment in the QRA was to predict the magnitude and frequency of potential human exposure to each COPC following the methodologies presented in **Section 8.1**. A conceptual site model (CSM) was developed which describes the potential receptors and exposure scenarios for the flowback water used in this exposure assessment. The potential exposures to receptors were evaluated based on the potential for a complete exposure pathway.

As discussed in **Section 8.2**, exposure point concentrations (EPCs) were derived for the theoretical assessment; empirical data were not available for evaluation. The EPCs for the theoretical assessment were calculated by estimating the mass and discharge flow of the COPCs in the flowback water.

C3.2 Human Health QRA

A human health hazard assessment was conducted according to the methodologies presented in **Section 8.4**. The purpose of the hazard assessment process was to summarise the environmental data, and to address the toxicological assessment of the COPCs that will be evaluated further in the risk assessment process.

Exposure assumptions for the human trespasser scenario were developed based on default or site-specific assumptions (**Section 8.4**). This receptor exposure pathway includes a small child to teenager

that may come in contact with the above grade water exposure scenario for approximately 20 days/year for a 10-year period with potential incidental ingestion [of 50 millilitres (ML) of water] and dermal contact (e.g., swimming where the whole body gets wet) for one half hour. The exposure parameters used in the QRA are presented on **Table 3**, attached.

Calculation of intake of COPCs was performed using the equations presented below:

Ingestion of water:

$$Intake\ (mg/kg-day)\ =\ (CW\ x\ IR\ X\ EF\ X\ ED)\ /\ (BW\ x\ AT)$$

Dermal contact with water:

$$Absorbed\ dose\ (mg/kg-day)\ =\ (CW\ x\ SA\ x\ DP\ x\ ET\ x\ EF\ x\ ED\ x\ CF)\ /\ (BW\ x\ AT)$$

Where:

CW = concentration in water (mg/l)
ET = exposure time (hr/day or hours/hours)
EF = exposure frequency (day/year)
ED = exposure duration (years)
CF = correction factor (1 x 10-3 l/cm3)
AT = averaging time (days)
IR = ingestion rate (l/hr)
BW = body weight (kg)
SA = skin surface area available for contact (cm2/d)
DP = dermal permeability factor (Kp – cm/hr).

C3.3 Toxicity Assessment

A toxicity assessment was conducted to determine the relationship between the dose of a COPC taken into the body, and the probability that an adverse effect will result from that dose. Quantitative estimates of the potency of COPCs include two sets of toxicity values, one for genotoxic carcinogens and one for other non-genotoxic carcinogens and non-carcinogenic effects. As discussed in **Section 8.4**, detailed toxicological profiles were developed for the chemicals. The toxicological profiles are included as **Appendix F9**.

The assessment of toxicity of the COPCs was used to develop initial screening criteria for human health exposure scenarios as discussed in **Section 8.4**. The derivation of Oral Reference Dose and Drinking Water Guideline Values are presented in **Table 4**, attached.

C3.4 Exposure Point Concentration

As presented above, the exposure scenarios are based on anticipated conditions, and the potential for exposure to the theoretical estimate of exposure. EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations and the existing environmental conditions within the fracturing fluids flowback storage ponds, and the flowback used in the irrigation fields.

To assess the potential flux of hydraulic fracturing chemicals to the environment, vendor disclosures for the hydraulic fracturing fluid systems were reviewed, and the chemical concentrations of key inputs were determined.

For the theoretical calculations, the mass and estimated chemical concentrations of the COPCs in the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System, as presented in **Table C9-1**, were used to estimate the potential concentrations in water within the fracturing fluids sump or flare pit, or flowback storage ponds. Based on stimulation flow back monitoring conducted by Santos and the QRA completed

for the Schlumberger Fluid Systems (**Appendix C**), 20 percent (%) of the total mass of constituents injected is assumed to be recovered in the flowback water. This mass is diluted within 150 % of the injected volume (the minimum volume that must be flowed back) to establish an "estimated" concentration (i.e., concentration expected due to full dilution of the back flow water) within the flowback storage ponds.

The flowback water will be contained within the flowback storage ponds for a projected maximum period of one year of operational activity before transfer or conveyance to the water treatment facilities and or transferred into Santos water convenyance systems (for treatment) and thereby blended with other coal seam gas (CSG) water not containing these constituents. To be conservative it has been assumed that the fluids are stored with ponds with theconcentration of COPCs in the flowback storage pond water adjusted, where applicable, to account for the biodegradation and photolytic degradation of constituents over time. The biodegradation information was obtained from the Organisation for Economic Cooperation and Development (OECD) ready tests (OECD, 1992) that were developed as a first-tier testing scheme to provide preliminary screening of organic chemicals. The ready tests are stringent screening tests that are conducted under aerobic conditions in which a high concentration of the test substance is used, and biodegradation is measured by non-specific parameters including dissolved organic carbon, biochemical oxygen demand and carbon dioxide production. **Table 5**, attached, presents the environmental fate information that was used to assess biodegradation of COPCs, and that was applied at the time periods of 0, 30, 150 and 300 days from initial flowback.

The water quality data derived using these assumptions for the theoretical COPCs are presented in **Table C9-1**.

The theoretical EPCs for the four exposure time periods (0, 30, 150 and 300 days) were compared to human health toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C9-2**.

C3.5 Risk Estimation

Risk estimation was performed in accordance with the methodologies outlined in Section 8.4 of the RA Compendium. The total target risk range for carcinogens was 1×10^{-4} to 1×10^{-6}; the target HI for non-threshold effects is less than or equal to 1.0.

No carcinogenic compounds are present in the stimulation fluids injected into the subsurface and as a result, only non-carcinogenic risks were calculated.

The results of the theoretical assessments for Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System for the trespasser exposure scenarios (day 0 and day 150, Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System events) are summarized in **Tables 6** and **7**, attached. As discussed above, the theoretical assessment was only conducted at the well pad sites.

The exposure scenarios include the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System event, as presented in **Table C9-1** for day 0 and day 150 from the flowback storage tank. The trespasser for day 0 had no unacceptable risks for the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System (HI=0.04, **Table 6**, attached), and for day 150 (HI=0.028, **Table 7**, attached). There were no unacceptable risks for either day scenario.

On this basis and using the theoretical concentrations, on this basis and using the theoretical concentrations, no adverse effects are predicted on trespassers.

C3.6 Ecological Risk Assessment

As discussed in **Section 8.5**, a screening level ecological risk assessment (ERA) was conducted to evaluate the potential for adverse ecological effects to terrestrial and aquatic ecological receptors that may be exposed to residual levels of hydraulic fracturing fluids in surface water used in the CSG fields.

C3.7 Exposure Assessment

Terrestrial receptors evaluated in the ERA include domesticated livestock, large mammalian wildlife and small mammalian wildlife. Beef cattle were used to evaluate domesticated livestock, kangaroos evaluated for large mammalian wildlife, and dingos for small mammalian wildlife. Aquatic receptors evaluated included invertebrates and fishes.

The estimate for dose-based or intake rates for the assessment endpoints for wildlife representing domestic livestock and native mammalian species used the following general equation:

TI = Cwater x IRwater x EF x ED / BW x ED x 365 days/year

Where:

TI = Total intake of COPC (mg/kg/day)
Cwater = Concentration of COPC in water (mg/l)
IRwater = Ingestion rate (litres/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
BW = Body weight (kg).

The exposure assumptions are presented in **Tables 8** through **10**, attached.

C3.8 Toxicity Assessment

To evaluate the potential for adverse ecological effects, toxicity reference values (TRVs) are selected as measurement endpoints for the ERA that will be used in the risk analysis. The TRVs are based on COPC levels that imply no adverse effects or levels that represent the lowest concentration at which adverse effects may occur. The ERA used two types of TRVs (Section 8.5.3 of the RA Compendium). The first TRV is a concentration-based TRV to evaluate the concentration of the selected COPC in the surface water and direct exposure by the aquatic ecological receptor. The determination of TRVs for freshwater was conducted according to the predicted no-effects concentration (PNEC) guidance in the Environmental Risk Assessment Guidance Manual for Industrial Chemicals prepared by the Australian Environmental Agency (AEA, 2009). As discussed in **Section 8.4**, detailed environmental profiles were developed for the chemicals. The environmental profiles are included in the risk dossiers in **Appendix G**. **Table 11**, attached, presents the COPC, the endpoint, NOEC [milligrams per litre (mg/L)], assessment factor, and the aquatic PNEC (mg/L). The second TRV is a dose-based TRV to evaluate the intake dose of the selected COPC from exposure to surface water by ingestion. The calculated TRVs for each of the mammalian ecological receptors evaluated in the ERA are presented in the species-specific ecological risk models.

C3.9 Exposure Point Concentration

EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations. The potentially affected flowback water that represents complete exposure pathways for the ecological receptors includes the surface water systems (e.g., flowback storage ponds and mud pits) that were used to estimate the EPCs for the human health receptors. The EPCs for the ecological receptors were estimated assuming the same scenarios, with exposure occurring in the irrigation area where irrigation water may pool and wildlife may drink from the standing water. **Table C9-**

1 presents the calculated EPCs for the ecological receptor exposure scenarios. The theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days) were compared to ecological based toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C9-3**.

Risks were characterised in accordance with the methodologies discussed in Section 8.5.6 of the RA Compendium. The resulting ecological hazard quotient must be less than or equal to 1.0 for risks to be considered acceptable.

C3.10 Estimation of Risk

The HI calculated for flowback water for aquatic risk were elevated above the acceptable level for the majority of COPCs evaluated (**Table C9-3**). Where large discharges of flowback water occur to surface water and/or flux dilution within the surface-water was insufficient, potential impacts on aquatic receptors could occur. As noted in the toxicity assessment section above, the lack of a robust aquatic toxicological database resulted in highly conservative aquatic screening values for the theoretical exposure scenario COPCs to be conservatively very low.

The results of the theoretical assessments for Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System for the livestock cattle, kangaroo and dingo are summarized in **Tables 12** through **17**, attached. The exposure scenarios include the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System EPCs presented in **Table C9-1**for day 0 and day 150 from the fracturing fluid well flowback. The modelled risks from Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System chemicals in the flowback water were acceptable for the livestock (HI=0.15 to 0.14, **Table 12** and **13**, attached), kangaroo (HI=0.031 0.029, **Table 14** and **15**, attached), and dingo (HI=0.013 to 0.012, **Table 16** and **17**, attached), for all exposure scenarios.

C4.0 Summary of QRA Findings

The QRA was completed as discussed in **Section 8.0**. An assessment was conducted using highly conservative theoretical calculations based on the chemicals utilised by Halliburton in hydraulic fracturing. This assessment assumed that a range of theoretical concentrations of injected chemicals would be present in the flowback water based on biodegradation rates, where applicable.

Consistent with the risk assessment and groundwater fate and transport modelling conducted by Golder, no potentially complete exposure pathways were identified for groundwater. Potential exposures are limited to the aboveground storage and handling of flowback water as part of the CSG Water Management Plan (WMP). Management of CSG water involves the temporary storage of flowback water in flowback storage ponds.

The exposure scenario modelled for the QRA was a trespasser being exposed to flowback water under various EPC scenarios. Based on quantitative risk calculations, the potential risks for the trespasser were acceptable for the EPC scenarios. There were no carcinogenic risks identified.

The modelled risks from Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System chemicals in the flowback water were acceptable for the livestock cattle, kangaroo, and dingo for all EPC exposure scenarios.

Potential impacts could occur if releases of flowback water were to occur to aquatic environments. Based on the use of low permeability materials (clay liners) and operational controls that limit the potential for turkey nest and dam overflows, the potential for these risks are also considered limited.

A combination of management and operational controls are being implemented to eliminate and control the potential for exposures. These include:

- Worker training and hazard identification
- Use of appropriate personal protective equipment (gloves, etc.)
- Flowback storage pond fencing to prevent entry of livestock and native fauna and minimise trespassing
- Use of low permeability materials or dam liners and routine dam inspections to prevent releases from flowback storage ponds
- Routine operational and security patrols to prevent trespassing.

C5.0 Conclusions

A weight-of-evidence evaluation of potential risks as described in **Section 5.0** was performed for the Halliburton Fluorescein Dye Hydraulic Fracturing Fluid System. Based on the qualitative and quantitative risk characterisations, the overall risk to human health and the environment is acceptable. Existing operational control activities employed by Santos are in place that will limit the potential risks to human health and the environment. These measures include:

- Occupational health and safety procedures implemented during hydraulic fracturing operations to prevent workers from direct contact with chemicals during spills and when handling flowback water or sediments;
- Environmental authority conditions that preclude the construction of well pads within 100 metres of a watercourse of water body;
- Implementation of spill containment procedures during operations to prevent migration of and exposure to chemicals;
- Disposal or capping of sediments contained within drained mud pits and turkey nests , to prevent exposure to contaminates in windborne dust;
- Fencing of drill pads to prevent trespassers and installation of signs to indicate that the water in the turkeys nest and mud pit is not potable and may contain contaminants;
- Installation and maintenance of fences around the well pad to prevent access to the drill pad by livestock and large native fauna;
- Santos operational procedures to ensure well integrity and design of fracture to stay within the target seam; and
- Mud pits and turkeys nests with clay liners, or similar material, to prevent seepage of flowback water into underlying aquifers.

Monitoring of water supply bores and surface water for a representative suite of chemicals within 2 kilometre of wells (and 200 m vertical separation) that are fractured will be conducted (as needed) to confirm the conclusion of incomplete exposure pathways and low risk.

No additional risks, other than those previously discussed, were identified with the chemicals or systems employed in hydraulic fracturing. Evaluation of other potential risks associated with hydraulic fracturing (i.e., noise and vibration) was conducted. Refer to **Section 9.0** for methodology specifics and results of this evaluation.

Tables

Table 2: PBT Assessment of the Halliburton Fluorescein Dye Fluid System

Substance	P/vP criteria fulfilled?	B/vB criteria fulfilled?	T criteria fulfilled?	Overall conclusion
Potassium chloride (14808-60-7)	Not applicable (inorganic salt)	No (estimated)	No (screening data available)	Not PBT (based on screening data and estimation)

Santos

Appendix C10
Condor Energy Services
Hydraulic Fracturing Fluid System

C1.0 Introduction

Santos Ltd. (Santos) is looking to use a borate, guar-based crosslinked Condor Energy Services hydraulic fracturing fluid system (the fluid system) for development of coal seam gas (CSG) resources in the Surat and Bowen Basins of Queensland. The disclosure for Condor Energy Services hydraulic fracturing fluid system, including a listing of the chemical constituents and percent of total volume in the fluid system, is provided in **Appendix C10-1**.

As presented in **Section 5.0** of the Hydraulic Fracturing Risk Assessment, Santos used a weight-of-evidence approach to evaluate the potential for human health and environmental (e.g., ecological) risks as a result of the hydraulic fracturing processes and the use of the Condor Energy Services hydraulic fracturing fluid system.

EHS Support, LLC (EHS Support) conducted a Quantitative Risk Assessment (QRA) to meet Conditions 49e and 49f of the 2 October 2011 approval under the *Environmental Protection and Biodiversity Conservation Act 1999* (EPBC 2008/4059) and the Environmental Amendment (EA) conditions to assess the toxicity of the mixtures.

The results and conclusions of the qualitative risk assessment components and the QRA are presented below. Refer to **Section 6.0** through **Section 8.0** for detailed discussions on the methodologies employed for the qualitative risk assessment and QRA components, which are referenced in the sections below.

C2.0 Qualitative Risk Assessment and Evaluation

C2.1 Chemicals Evaluated

The Condor Energy Services hydraulic fracturing fluid system was assessed. The list of individual chemicals assessed is presented in **Table 1** below. A mass balance of the chemicals is provided as **Table C10-1**.

Information regarding the chemical and physical properties of the individual chemicals listed below as well as the approximate percentage present in the hydraulic fracturing system can be found on the Safety Data Sheets in **Appendix E**.

The fluid system does not contain BTEX (benzene, toluene, ethylbenzene, xylenes) or polycyclic aromatic hydrocarbons (PAHs) based on EHS Support's understanding that Condor Energy has tested all their products. Field monitoring will also be conducted in accordance with regulatory requirements. While none of the fracturing fluid chemicals identified contain BTEX or PAHs, PAHs occur naturally in coal and it is possible that certain PAHs may naturally be present in the coal seam groundwater used in the hydraulic fracturing process.

Table 1: Hydraulic fracturing chemicals

Chemical	CAS Number
Alcohols, C9-11, ethoxylated	68439-46-3
Ethoxylated C11 Alcohol	34398-01-1
Ethylene Glycol	107-21-1
Choline Chloride	67-48-1
Glutaraldehyde	111-30-8
Ammonium Sulphate	7783-20-2
Polyacrylamide	25085-02-3
Sodium polyacrylate	9003-04-7
Sodium bisulfite	7631-90-5
2-Propenoic acid, homopolymer, ammonium salt	9003-03-6
Ammonium Persulphate	7727-54-0
Potassium persulfate	7727-21-1
2-Ethoxy-naphthalene	93-18-5
Potassium Hydroxide	1310-58-3
Inorganic Salt	584-08-7
Glycerol	56-81-5
Sodium Tetraborate	1330-43-4
Sodium Hydroxide	1310-73-2
Hemicellulase	9025-56-3
Amylase, Alpha	9000-90-2
Sodium Benzoate	532-32-1
Pottasium Sorbate	24634-61-5
DISTILLATES, HYDROTREATED LIGHT	64742-47-8
Guar Gum	9000-30-0
Polyoxyethylene nonylphenol ether	9016-45-9
Quaternary ammonium compounds, bis(hydrogenated tallow alkyl)dimethyl, salts with bentonite	68953-58-2
1,6-Hexanediol	629-11-8
HydroChloric Acid	7647-01-0
Cinnamaldehyde	104-55-2

Chemical	CAS Number
Tar Bases, Quinoline Derivatives, Benzyl Chloride-Quat	72480-70-7
Castor Oil	61791-12-6
Isopropanol	67-63-0
Pine Oil	8002-09-3
N-Benzyl-Alkylpyridinium Chloride	68909-18-2
Water in Additive	7732-18-5
2-Mercaptoethyl Alcohol	60-24-2

Diethylene Glycol	111-46-6
Methanol	67-56-1
Formic Acid	64-18-6
Sodium erythorbate	6381-77-7
Acetic Acid	64-19-7
Potassium Chloride	7447-40-7

C2.2 Risk Assessment Framework and Findings

As discussed in **Section 5.0**, a systematic weight of evidence approach was utilised to complete the risk assessment for the Condor Energy Services hydraulic fracturing fluid system. The work has involved the following evaluations:

Qualitative Assessment Methodologies

- PBT Assessment
- Exposure Assessment
- Mass Balance of Fluid System
- Fate and Transport Modelling

Quantitative Risk Assessment Methodologies

- Quantitative Human Health Risk Assessment (HHRA)
- Quantitative Ecological Risk Assessment for Terrestrial and Aquatic Receptors
-

C2.3 PBT Assessment

For the environmental hazard assessment, a PBT (persistence, bioaccumulative, toxicity) assessment was conducted in accordance with the guidance developed by DEWHA (2009), as presented in the **Section 6.1**. The PBT assessment is conducted because of specific concerns for substances that can be shown to persist for long periods in the environment, to bioaccumulate in food chains, and can give rise to toxic effects after a longer time and over a greater spatial scale than chemicals without these properties. These effects may be difficult to detect at an early stage because of long-term exposures at normally low concentration levels and long life-cycles of species at the top of the food chain.

The PBT approach outlined in **Section 6.1** was undertaken to rank the hydraulic fracturing chemicals based on PBT potential. As a result of this assessment, no chemical constituents identified in the Condor Energy Services hydraulic fracturing fluid system were classified as a PBT chemical and are therefore not considered to be inherently hazardous. The results of the PBT Assessment are presented in **Table 2**, attached.

C2.3 Exposure Assessment

As discussed in **Section 7.0**, the exposure assessment identified receptors potentially exposed to chemicals of potential concern (COPCs) identified for the study and outlined the exposure pathways by which the receptors may come in to contact with the COPCs. A detailed exposure assessment was not conducted in the qualitative risk assessment.

C2.4 Mass Balance of Fluid System

A quantitative mass balance calculation was undertaken to identify the amount of each chemical additive of the hydraulic fracturing fluid system. The results of the mass balance calculations are presented in **Table C10-1**.

C2.5 Fate and Transport Modelling

As discussed in **Section 7.2**, fate and transport modelling was conducted on a range of key constituents of interest in typical hydraulic fracturing fluid systems. These results provided the framework for assessing potential mobility of all constituents used in hydraulic fracturing. The modelling demonstrated that despite the variability in chemical properties between fluid systems there is limited potential for chemicals to migrate within the coal seams. Refer to **Section 7.2** for further details.

C3.0 Quantitative Risk Assessment

In accordance with the methodologies presented in **Section 8.0**, a QRA was conducted on theoretical datasets for those chemicals identified in the Condor Energy Services hydraulic fracturing fluid system. The QRA approach evaluates the toxicity of the individual substances and characterises the cumulative risks of the total effluent toxicity and ecotoxicity.

Generally, this methodology includes the identification of the hazards posed by constituents in the flowback water, compilation of the toxicity criteria for each constituent, development of exposure models to estimate the daily intake of the constituents, and calculations of individual constituent hazard quotients (daily intake divided by the toxicity criteria) and a cumulative constituent hazard index (HI) for each potentially complete exposure pathway for each human or terrestrial receptor.

Potential complete exposure pathways to the storage of flowback from hydraulically stimulated wells, and potential risks to humans, terrestrial and aquatic receptors from the potential storage and accidental releases are evaluated in the QRA.

No further assessment of groundwater was determined to be necessary due to lack of potentially complete exposure pathways. Detailed operational procedures have been provided that are designed to contain the hydraulic fracturing fluids within the coal sequences, and no connection exists between groundwater in the coal seams and surface-water or springs (and therefore Matters of National Environmental Significance [MNES]). Further, the potential risks to workers involved with the hydraulic fracturing process were not considered as detailed Health and Safety (H&S) procedures are employed to manage exposures. The QRA considered the following specific exposure pathways:

1. Exposure of trespassers to flowback water contained within flowback storage ponds.
2. Exposure of terrestrial receptors (e.g., livestock and wildlife) to flowback water contained within the flowback storage tank.
3. Exposure of aquatic receptors to flowback water in the situation of an accidental release, such as from piping or a release from the flowback storage tank. These potential releases could include a failure of containment systems, overtopping of the dam or in an extreme situation (considered highly unlikely) structural failure of the dam itself.

C3.1 Exposure Assessment

The purpose of the exposure assessment in the QRA was to predict the magnitude and frequency of potential human exposure to each COPC following the methodologies presented in **Section 8.1**. A conceptual site model (CSM) was developed which describes the potential receptors and exposure scenarios for the flowback water used in this exposure assessment. The potential exposures to receptors were evaluated based on the potential for a complete exposure pathway.

As discussed in **Section 8.3**, exposure point concentrations (EPCs) were derived for the theoretical assessment; empirical data were not available for evaluation. The EPCs for the theoretical assessment were calculated by estimating the mass and discharge flow of the COPCs in the flowback water.

C3.2 Human Health QRA

A human health hazard assessment was conducted according to the methodologies presented in **Section 8.4**. The purpose of the hazard assessment process was to summarise the environmental data, and to address the toxicological assessment of the COPCs that will be evaluated further in the risk assessment process.

Exposure assumptions for the human trespasser scenario were developed based on default or site-specific assumptions (**Section 8.4**). This receptor exposure pathway includes a small child to teenager

that may come in contact with the above grade water exposure scenario for approximately 20 days/year for a 10-year period with potential incidental ingestion [of 50 millilitres (ML) of water] and dermal contact (e.g., swimming where the whole body gets wet) for one-half hour. The exposure parameters used in the QRA are presented on **Table 3**, attached.

Calculation of intake of COPCs was performed using the equations presented below:

Ingestion of water:

$$Intake\ (mg/kg-day)\ =\ (CW\ x\ IR\ X\ EF\ X\ ED)\ /\ (BW\ x\ AT)$$

Dermal contact with water:

$$Absorbed\ dose\ (mg/kg-day)\ =\ (CW\ x\ SA\ x\ DP\ x\ ET\ x\ EF\ x\ ED\ x\ CF)\ /\ (BW\ x\ AT)$$

Where:

AT = averaging time (days)
BW = body weight (kg)
CF = correction factor (1 x 10-3 l/cm3)
CW = concentration in water (mg/l)
DP = dermal permeability factor (Kp – cm/hr).
ED = exposure duration (years)
EF = exposure frequency (day/year)
ET = exposure time (hr/day or hours/hours)
IR = ingestion rate (l/hr)
SA = skin surface area available for contact (cm2/d)

C3.3 Toxicity Assessment

A toxicity assessment was conducted to determine the relationship between the dose of a COPC taken into the body, and the probability that an adverse effect will result from that dose. Quantitative estimates of the potency of COPCs include two sets of toxicity values, one for genotoxic carcinogens and one for other non-genotoxic carcinogens and non-carcinogenic effects. As discussed in **Section 8.4**, detailed toxicological profiles were developed for the chemicals. The toxicological profiles are included as **Appendix F10**.

The assessment of toxicity of the COPCs was used to develop initial screening criteria for human health exposure scenarios as discussed in **Section 8.4**. The derivation of Oral Reference Dose and Drinking Water Guideline Values are presented in **Table 4**, attached. Australian Drinking Water Screening Values for the COPCs are also presented on **Table 4**, attached.

C3.4 Exposure Point Concentration

As presented above, the exposure scenarios are based on anticipated conditions, and the potential for exposure to the theoretical estimate of exposure. EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations and the existing environmental conditions within the fracturing fluids flowback storage ponds, and the flowback used in the irrigation fields.

To assess the potential flux of hydraulic fracturing chemicals to the environment, vendor disclosures for the hydraulic fracturing fluid systems were reviewed, and the chemical concentrations of key inputs were determined.

For the theoretical calculations, the mass and estimated chemical concentrations of the COPCs in the Condor Energy Services hydraulic fracturing fluid system, as presented in **Table C10-1**, were used to estimate the potential concentrations in water within the fracturing fluids sump or flare pit, or flowback

storage ponds. Based on stimulation flow back monitoring conducted by Santos and the QRA completed for the Schlumberger Fluid Systems (**Appendix C**), 20 percent (%) of the total mass of constituents injected is assumed to be recovered in the flowback water. This mass is diluted within 150 % of the injected volume (the minimum volume that must be flowed back) to establish an "estimated" concentration (i.e., concentration expected due to full dilution of the back-flow water) within the flowback storage ponds.

The flowback water will be contained within the flowback storage ponds for a projected maximum period of one year of operational activity before transfer or conveyance to the water treatment facilities and or transferred into Santos water conveyance systems (for treatment) and thereby blended with other conveyance systems water not containing these constituents. To be conservative it has been assumed that the fluids are stored with ponds with the concentration of COPCs in the flowback storage pond water adjusted, where applicable, to account for the biodegradation and photolytic degradation of constituents over time. The biodegradation information was obtained from the Organisation for Economic Cooperation and Development (OECD) ready tests (OECD, 1992) that were developed as a first-tier testing scheme to provide preliminary screening of organic chemicals. The ready tests are stringent screening tests that are conducted under aerobic conditions in which a high concentration of the test substance is used, and biodegradation is measured by non-specific parameters including dissolved organic carbon, biochemical oxygen demand and carbon dioxide production. **Table 5**, attached, presents the environmental fate information that was used to assess biodegradation of COPCs, and that was applied at the time periods of 0, 30, 150 and 300 days from initial flowback.

The water quality data derived using these assumptions for the theoretical COPCs are presented in **Table C10-1**.

The theoretical EPCs for the four exposure time periods (0, 30, 150 and 300 days) were compared to human health toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C10-2**.

C3.5 Risk Estimation

Risk estimation was performed in accordance with the methodologies outlined in **Section 8.4**. The total target risk range for carcinogens was 1×10^{-4} to 1×10^{-6}; the target HI for non-threshold effects is less than or equal to 1.0.

The results of the theoretical assessments for Condor Energy Services hydraulic fracturing fluid system for the trespasser exposure scenarios (day 0 and day 150, Condor Energy Services hydraulic fracturing fluid system events) are summarized in **Tables 6 and 7**, attached. As discussed above, the theoretical assessment was conducted at the well pad sites.

The exposure scenarios include the Condor Energy Services hydraulic fracturing fluid system event, as presented in **Table C10-1** for day 0 and day 150 from the flowback storage tank. The trespasser for day 0 had risks slightly above the target of 1.0 for the Condor Energy Services hydraulic fracturing fluid system (HI=3.6, **Table 6**, attached), and for day 150 (HI=1.7, **Table 7**, attached). The elevated HI were due to the dermal exposure pathway for distiilates, hydrotreated light.

On this basis and using the theoretical concentrations, on this basis and using the theoretical concentrations, no adverse effects are predicted on trespassers.

C3.6 Ecological Risk Assessment

As discussed in **Section 8.5**, a screening level ecological risk assessment (ERA) was conducted to evaluate the potential for adverse ecological effects to terrestrial and aquatic ecological receptors that may be exposed to residual levels of hydraulic fracturing fluids in surface water used in the CSG fields.

C3.7 Exposure Assessment

Terrestrial receptors evaluated in the ERA include domesticated livestock, large mammalian wildlife and small mammalian wildlife. Beef cattle were used to evaluate domesticated livestock, kangaroos evaluated for large mammalian wildlife, and dingos for small mammalian wildlife. Aquatic receptors evaluated included invertebrates and fishes.

The estimate for dose-based or intake rates for the assessment endpoints for wildlife representing domestic livestock and native mammalian species used the following general equation:

TI = Cwater x IRwater x EF x ED / BW x ED x 365 days/year

Where:

TI = Total intake of COPC (mg/kg/day)
Cwater = Concentration of COPC in water (mg/l)
IRwater = Ingestion rate (litres/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
BW = Body weight (kg)

The exposure assumptions are presented in **Tables 8** through **10**, attached.

C3.8 Toxicity Assessment

To evaluate the potential for adverse ecological effects, toxicity reference values (TRVs) are selected as measurement endpoints for the ERA that will be used in the risk analysis. The TRVs are based on COPC levels that imply no adverse effects or levels that represent the lowest concentration at which adverse effects may occur. The ERA used two types of TRVs (**Section 8.5.3**). The first TRV is a concentration-based TRV to evaluate the concentration of the selected COPC in the surface water and direct exposure by the aquatic ecological receptor. The determination of TRVs for freshwater was conducted according to the predicted no-effects concentration (PNEC) guidance in the Environmental Risk Assessment Guidance Manual for Industrial Chemicals prepared by the Australian Environmental Agency (AEA, 2009). As discussed in **Section 8.4**, detailed environmental profiles were developed for the chemicals. The environmental profiles are included in the risk dossiers in **Appendix G**. **Table 11**, attached, presents the COPC, the endpoint, NOEC [milligrams per litre (mg/L)], assessment factor, and the aquatic PNEC (mg/L). The second TRV is a dose-based TRV to evaluate the intake dose of the selected COPC from exposure to surface water by ingestion. The calculated TRVs for each of the mammalian ecological receptors evaluated in the ERA are presented in the species-specific ecological risk models.

C3.9 Exposure Point Concentration

EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations. The potentially affected flowback water that represents complete exposure pathways for the ecological receptors includes the surface water systems (e.g., flowback storage ponds and mud pits) that were used to estimate the EPCs for the human health receptors. The EPCs for the ecological receptors were estimated assuming the same scenarios, with exposure occurring in the irrigation area where irrigation water may pool and wildlife may drink from the standing water. **Table C10-1** presents the calculated EPCs for the ecological receptor exposure scenarios. The theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days) were compared to ecological based toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C10-3**.

Risks were characterised in accordance with the methodologies discussed in **Section 8.5.6**. The resulting ecological hazard quotient must be less than or equal to 1.0 for risks to be considered acceptable.

C3.10 Estimation of Risk

The HI calculated for flowback water for aquatic risk were elevated above the acceptable level for the majority of COPCs evaluated (**Table C10-3**). Where large discharges of flowback water occur to surface water and/or flux dilution within the surface-water was insufficient, potential impacts on aquatic receptors could occur. As noted in the toxicity assessment section above, the lack of a robust aquatic toxicological database resulted in highly conservative aquatic screening values for the theoretical exposure scenario COPCs to be conservatively very low.

The results of the theoretical assessments for Condor Energy Services hydraulic fracturing fluid system for the livestock cattle, kangaroo and dingo are summarized in **Tables 12** through **17**, attached. The exposure scenarios include the Condor Energy Services hydraulic fracturing fluid system EPCs presented in **Table C10-1** for day 0 and day 150 from the fracturing fluid well flowback. The modelled risks from Condor Energy Services hydraulic fracturing fluid system chemicals in the flowback water were slightly above the target of 1.0 for the cattle (HI=2.1, **Table 12**, attached), but were acceptable for the modelled values for day 150 (HI = 0.024, **Table 13**, attached), and all exposure scenarios for the kangaroo (HI=0.44 0.005, **Table 14** and **15**, attached), and dingo (HI=0.18 to 0.002, **Table 16** and **17**, attached).

C4.0 Summary of QRA Findings

The QRA was completed as discussed in **Section 8.0**. An assessment was conducted using highly conservative theoretical calculations based on the chemicals utilised by Schlumberger in hydraulic fracturing. This assessment assumed that a range of theoretical concentrations of injected chemicals would be present in the flowback water based on biodegradation rates, where applicable.

Consistent with the risk assessment and groundwater fate and transport modelling conducted by Golder, no potentially complete exposure pathways were identified for groundwater. Potential exposures are limited to the aboveground storage and handling of flowback water as part of the CSG Water Management Plan (WMP). Management of CSG water involves the temporary storage of flowback water in flowback storage ponds.

The exposure scenario modelled for the QRA was a trespasser being exposed to flowback water under various EPC scenarios. Based on quantitative risk calculations, the potential risks for the trespasser were slightly unacceptable for the EPC scenarios. The QRA used very conservative exposure assumptions. There were no carcinogenic risks identified.

The modelled risks from Condor Energy Services hydraulic fracturing fluid system chemicals in the flowback water were unacceptable for the livestock cattle on day 0, but were acceptable for cattle on day 150, and all EPC exposure scenarios for the kangaroo, and dingo.

Similarly, potential impacts could occur if releases of flowback water were to occur to aquatic environments. Based on the use of low permeability materials (clay liners) and operational controls that limit the potential for turkey nest and dam overflows, the potential for these risks are also considered limited.

A combination of management and operational controls are being implemented to eliminate and control the potential for exposures. These include:

- Worker training and hazard identification
- Use of appropriate personal protective equipment (gloves, etc.)
- Flowback storage pond fencing to prevent entry of livestock and native fauna and minimise trespassing
- Use of low permeability materials or dam liners and routine dam inspections to prevent releases from flowback storage ponds
- Routine operational and security patrols to prevent trespassing

C5.0 Conclusions

A weight-of-evidence evaluation of potential risks as described in **Section 5.0** was performed for the Condor Energy Services hydraulic fracturing fluid system. Based on the qualitative and quantitative risk characterisations, the overall risk to human health and the environment is acceptable. Existing operational control activities employed by Santos are in place that will limit the potential risks to human health and the environment. These measures include:

- Occupational health and safety procedures implemented during hydraulic fracturing operations to prevent workers from making direct contact with chemicals during spills and when handling flowback water or sediments
- Environmental authority conditions that preclude the construction of well pads within 100 metres of a watercourse of water body
- Implementation of spill containment procedures during operations to prevent migration of and exposure to chemicals
- Disposal or capping of sediments contained within drained mud pits and turkey nests, to prevent exposure to contaminates in windborne dust
- Fencing of drill pads to prevent trespassers from entering and installation of signs to indicate that the water in the turkey nests and mud pit is not potable and may contain contaminants
- Installation and maintenance of fences around the well pad to prevent access to the drill pad by livestock and large native fauna
- Santos operational procedures to ensure well integrity and design of fracture to stay within the target seam
- Mud pits and turkey nests with clay liners, or similar material, to prevent seepage of flowback water into underlying aquifers

Monitoring of water supply bores and surface water for a representative suite of chemicals within 2 kilometres of the wells (and 200 m vertical separation) that are fractured will be conducted (as needed) to confirm the conclusion of incomplete exposure pathways and low risk.

No additional risks, other than those previously discussed, were identified with the chemicals or systems employed in hydraulic fracturing. Evaluation of other potential risks associated with hydraulic fracturing (i.e., noise and vibration) was conducted. Refer to **Section 9.0** for methodology specifics and results of this evaluation.

.

Amylase, alpha (9000-90-2)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Castor oil, ethoxylated (61791-12-6)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Choline chloride (67-48-1)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Cinnamaldehyde (104-55-2)	No (screening data available)	No (screening data available)	Yes (screening data available)	Not PBT (based on screening data)
Diethylene glycol (111-46-6)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Distillates (petroleum), hydrotreated light (64742-47-8)	Yes (screening data available)	Yes (modeling data available)	No (screening and experimental data available	Not PBT (based on modeling, screening and experimental data)

Table 2: Condor Water Treatment PBT Assessment
Condor Energy Services Hydraulic Fracturing Fluid System

Substance	P/vP criteria fulfilled?	B/vB criteria fulfilled?	T criteria fulfilled?	Overall conclusion
Ethoxylated C11 alcohol (34398-01-1)	No (screening data available)	No (screening data available)	Yes (experimental data available)	Not PBT (based on screening data)
2-Ethyoxynaphthalene (93-18-5)	Yes (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Ethylene glycol (107-21-1)	No (screening data available)	No (experimental data available)	No (experimental data available)	Not PBT (based on screening and experimental data)
Formic acid (64-18-6)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Glutaraldehyde (111-30-8)	No (screening data available)	No (screening data available)	Yes (experimental data available)	Not PBT (based on screening and experimental data)
Glycerol (56-81-5)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Guar gum (9000-30-0)	No (estimated)	No (based on physico-chemical properties)	Potentially Yes (based on experimental data)	Not PBT (based on estimation, physico-chemical properties, experimental data)
Hemicellulase (9025-56-3)	No (screening data available)	No (based on physico-chemical properties)	No (screening data available)	Not PBT (based on screening data)
1,6-Hexanediol (629-11-8)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Hydrochloric acid (7647-01-0)	Not applicable (ionic species ubiquitous in environment)	No (essential ions to biological systems; actively regulated)	No (screening data available)	Not PBT (based on screening data and ubiquitous inorganic salt)
Isopropanol (67-63-0)	No (screening data available)	No (screening data available)	No (experimental data available)	Not PBT (based on screening data)
2-Mercaptoethyl alcohol (60-24-2)	No (experimental data available)	No (screening data available)	Yes (experimental data available)	Not PBT (based on screening and experimental data)

Table 2: Condor Water Treatment PBT Assessment
Condor Energy Services Hydraulic Fracturing Fluid System

Substance	P/vP criteria fulfilled?	B/vB criteria fulfilled?	T criteria fulfilled?	Overall conclusion
Methanol (67-56-1)	No (screening data available)	No (experimental data available)	No (screening data available)	Not PBT (based on screening and experimental data)
N-benzyl-alkylpyridium chloride (68909-18-2)	No data.	No (screening data available)	Yes (screening data available)	Not PBT (based on screening data)
Quat. Ammonium compds, bis (hydrogenated tallow alkyl) dimethyl, salts with bentonite (68955-58-2)	Yes (screening data available)	No (based on physico-chemical properties)	No (experimental data available)	Not PBT (based on screening and experimental data)
Pine oil (8002-09-3)	No (screening data available)	Potentially yes (screening data available on components)	No (screening data available)	Not PBT (based on screening and experimental data)
Polyoxyethylene nonylphenol ether (9016-45-9)	No (screening data available)	No (screening data available)	Yes (experimental data available)	Not PBT (based on screening and experimental data)
Polyoxyethylene-polyoxypropylene block copolymer (9003-11-6)	Yes (polymer, not readily biodegradable)	No (polymer, physico-chemical properties)	No (screening data available)	No (based on polymer, physico-chemical properties)
Potassium carbonate (584-08-7)	Not applicable (ionic species from inorganic salt is ubiquitous in environment)	No (ionic species)	No experimental data available)	Not PBT (based on experimental data and ionic species)
Potassium chloride (7447-40-7)	Not applicable (ionic species from inorganic salt is ubiquitous in environment)	No (ionic species)	No experimental data available)	Not PBT (based on experimental data and ionic species)
Potassium hydroxide (1310-73-2)	Not applicable (ionic species from inorganic salt is ubiquitous in environment)	No (ionic species)	No experimental data available)	Not PBT (based on experimental data and ionic species)

Table 2: Condor Water Treatment PBT Assessment
Condor Energy Services Hydraulic Fracturing Fluid System

Substance	P/vP criteria fulfilled?	B/vB criteria fulfilled?	T criteria fulfilled?	Overall conclusion
Potassium persulfate (7727-21-1)	Not applicable (ionic species ubiquitous in environment)	No (essential ions to biological systems; actively regulated)	No (screening data available)	Not PBT (based on screening data and ubiquitous inorganic salt)
Potassium sorbate (24634-61-5)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
2-Propenoic acid, homopolymer, ammonium salt (9003-03-6)	Yes (polymer, not readily biodegradable)	No (polymer, physico-chemical properties)	No (experimental data available)	Not PBT based on physico-chemical properties and experimental data)
Sodium benzoate (532-32-1)	No (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Sodium bisulfite (7631-90-5)	Not applicable (ionic species ubiquitous in environment)	No (essential ions to biological systems; actively regulated)	No (screening data available)	Not PBT (based on screening data and ubiquitous inorganic salt)
Sodium erythrobate (6381-77-7)	Yes (screening data available)	No (screening data available)	No (screening data available)	Not PBT (based on screening data)
Sodium hydroxide (1310-72-2)	Not applicable (ionic species from inorganic salt is ubiquitous in environment)	No (ionic species)	No experimental data available)	Not PBT (based on experimental data and ionic species)
Sodium polyacrylate ((9003-04-7)	Yes (polymer, not readily biodegradable)	No (polymer, physico-chemical properties)	No (experimental data available)	Not PBT based on physico-chemical properties and experimental data)
Sodium tetraborate decahydrate (1303-96-4)	Not applicable (ionic species from inorganic salt is ubiquitous in environment)	No (ionic species)	Yes (known or presumed human reproductive toxicant - GHS Cat. 1B)	Not PBT (based on experimental data and ionic species)
Tar bases, quinoline deriv., benzyl chloride – Quat. (72480-70-7)	No data	No data	No data	No data

PBT = persistence, bioaccumulative, toxicity

Table 3 Exposure Assumptions - Trespasser
Condor Energy Services Hydraulic Fracturing Fluid System

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/hr	0.05
	ET	Exposure time	hr/day	0.5
	EF	Exposure frequency	day/yr	20
	ED	Exposure duration	yr	10
	BW	Body weight	kg	47
	AT-NC	Averaging time - noncancer	days	3,650
	AT-C	Averaging time - cancer	days	25,550
Dermal	SA	Surface area for contact	cm^2/day	13,000
	DP	Dermal permeability factor	cm/h	chemical-specific
	ET	Exposure time	hr/day	1
	EF	Exposure frequency	day/yr	20
	ED	Exposure duration	yr	10
	BW	Body weight	kg	47
	AT-NC	Averaging time - noncancer	days	3,650
	AT-C	Averaging time - cancer	days	25,550
	CF	Conversion factor	l/cm^3	1.0E-03

Table 4: Condor Oral Reference Doses and Drinking Water Guidelines
Condor Energy Services Hydraulic Fracturing Fluid System

Constituent (CAS No.)	Study	Critical Effect/Target Organ(s)	NOAEL (mg/kg-day)	Uncertainty Factors	Oral Reference Dose (mg/kg-day)	Drinking Water Guideline (mg/L)
Acrylamide/sodium acrylate copolymer (25085-02-3)	2-yr rat dietary	No systemic effects.	5,000	100	50	175
Alcohols, C9-11, ethoxylated (68439-46-3)	90-day rat dietary	No systemic effects.	150	300	0.5	1.8
Amylase, alpha (9000-90-2)	13-wk rat oral gavage	No systemic effects.	1,110	300	4	13
Castor oil, ethoxylated (61791-12-6)	13-wk dietary	No systemic effects.	2,500	300	8	28
Choline chloride (67-48-1)	Human study	Slight hypotensive effect	107[a]	2	50[b]	175[b]
Cinnamaldehyde (104-55-2)	2-yr mouse dietary	↓ body weights	125	100	1.0	4
Diethylene glycol (111-46-6)	225-d rat dietary	Kidney toxicity	105	100	1.0	3.5
Distillates (petroleum), hydrotreated light (64742-47-8)	13-wk rat oral gavage	No systemic toxicity	1,000	300	3	12
Ethoxylated C11 alcohol (34398-01-1)	90-day rat dietary	No systemic effects.	150	300	0.5	1.8
2-Ethyoxynaphthalene (93-18-5)	90-day rat dietary	No systemic effects.	5	300	0.02	0.07
Ethylene glycol (107-21-1)	2-yr rat dietary	Kidney toxicity	150[c]	10	15	53
Formic acid (64-18-6)	1-yr. dietary	↓ body weights	220	100	2	7

Table 4: Condor Oral Reference Doses and Drinking Water Guidelines
Condor Energy Services Hydraulic Fracturing Fluid System

Constituent (CAS No.)	Study	Critical Effect/Target Organ(s)	NOAEL (mg/kg-day)	Uncertainty Factors	Oral Reference Dose (mg/kg-day)	Drinking Water Guideline (mg/L)
Glutaraldehyde (111-30-8)	2-yr rat drinking water	↓ body wt. gain, food consumption	4	100	0.04	0.14
Glycerol (56-81-5)	90-d rat dietary	Liver	4,580	1,000	4.6	16
Guar gum (9000-30-0)	2-yr rat dietary	↓ body weights	1,250	100	13	46
Hemicellulase (9025-56-3)	13-wk rat oral gavage	None	1,000	1,000	1.0	3.5
1,6-Hexanediol (629-11-8)	90-d rat oral gavage	↓ body weights	400	300	1.0	3.5
Isopropanol (67-63-0)	Rat 2-generation reproductive	Decrease male mating index	420[d]	1,000	0.4	1.4
2-Mercaptoethyl alcohol (60-24-2)	OECD 422	Liver, heart, reproductive effects	15	300	0.05	0.18
Methanol (67-56-1)	Mouse developmental	Increased cervical ribs per litter	43.1 mg/L[e]	100	2[e]	7
N-benzyl-alkylpyridium chloride (68909-18-2)	[f]	-	-	-	-	-
Pine oil (8002-09-3)	Rat developmental	↓ body weight gain and food consumption (maternal); ↓ fetal body weights, malformations, delayed ossification	50 (maternal, developmental)	300	0.17	0.6
Polyoxyethylene nonylphenol ether (9016-45-9)	[f]	-	-	-	-	-

Table 4: Condor Oral Reference Doses and Drinking Water Guidelines
Condor Energy Services Hydraulic Fracturing Fluid System

Constituent (CAS No.)	Study	Critical Effect/Target Organ(s)	NOAEL (mg/kg-day)	Uncertainty Factors	Oral Reference Dose (mg/kg-day)	Drinking Water Guideline (mg/L)
Polyoxyethylene-polyoxypropylene block copolymer (9003-11-6)	2-yr rat dietary	Reduced body weight gain	2,500	100	25	88
Potassium chloride (7447-40-7)	2-yr rat dietary	None	1,820	100	18	63
Potassium sorbate (24634-61-5)	2-yr rat dietary	Spleen, focal fatty changes	1,000	100	10	35
2-Propenoic acid, homopolymer, ammonium salt (9003-03-6)	4-wk rat dietary	No systemic toxicity	1,136	1,000	1.0	3.5
Quat. Ammonium compds, bis (hydrogenated tallow alkyl) dimethyl, salts with bentonite (68955-58-2)	12-wk rat dietary	↓ Food efficiency	2,500	300	8	29
Sodium benzoate (532-32-1)	90-d rat dietary	Mortality; ↓ body weights	3,145	300	10	35
Sodium bisulfite (7631-90-5)	2-yr rat dietary study	None	523	100	5	18
Sodium erythrobate (6381-77-7)	10-wk mouse drinking water	Spleen, kidney, liver effects	4,250	300	14	49
Sodium polyacrylate ((9003-04-7)	28-d rat dietary	None	1,136	1000	1	4
Sodium tetraborate decahydrate (1303-96-4)	Rat developmental	↓ Fetal body weights	10.3[g]	66	0.2	0.7
Tar bases, quinoline deriv., benzyl chloride – Quat. (72480-70-7)	[e]	-	-	-	-	-

Table 4: Condor Oral Reference Doses and Drinking Water Guidelines
Condor Energy Services Hydraulic Fracturing Fluid System

[a]LOAEL.
[b]Value for choline.
[c]Human Equivalent Dose derived from benchmark dose and PBPK modeling.
[d]Point of departure calculated for benchmark dose modeling.
[e]The Point of Departure (POD) value is the internal C_{max} methanol blood concentration obtained using BMD analysis from an inhalation study.
[f]No data.
[g]$BMDL_{50}$ (U.S. EPA IRIS).

Australian Drinking Water Guidance Values

Constituent (CAS No.)	Drinking Water Guideline	Drinking Water Guidance Value
Acetic acid (64-19-7)	pH	6.5 to 8.5
Ammonium persulfate (7727-54-0)	Sulfate	500 mg/L (health) and 250 mg/L (aesthetics)
Ammonium sulfate (7783-20-2)	Sulfate	500 mg/L (health) and 250 mg/L (aesthetics)
Hydrochloric acid (7647-01-0)	pH; chloride	6.5 to 8.5; 250 mg/L (aesthetics)
Potassium carbonate (584-08-7)	pH	6.5 to 8.5
Potassium hydroxide (1310-73-2)	pH	6.5 to 8.5
Potassium persulfate (7727-21-1)	Sulfate	500 mg/L (health) and 250 mg/L (aesthetics)
Sodium hydroxide (1310-72-2)	Sodium; pH	180 mg/L (aesthetic); 6.5 to 8.5

Table 5 Environmental Fate Information
Condor Energy Services Hydraulic Fracturing Fluid System

Acetic acid	Dissociates completely in aqueous media; acetate ion is readily biodegradable (half-life = 15 days)[a]
Acrylamide/sodium acrylate copolymer	Not biodegradable.
Alcohols, C9-11, ethoxylated	Readily biodegradable (half-life = 15 days)[a]
Ammonium persulfate	Dissociates completely in aqueous media
Ammonium sulfate	Dissociates completely in aqueous media
Amylase, alpha	Readily biodegradable (half-life = 15 days)[a]
Castor oil, ethoxylated	Readily biodegradable (half-life = 15 days)[a]
Choline chloride	Readily biodegradable (half-life = 15 days)[a]
Cinnamaldehyde	Readily biodegradable (half-life = 15 days)[a]
Diethylene glycol	Readily biodegradable (half-life = 15 days)[a]
Distillates (petroleum), hydrotreated light	Inherently biodegradable (half-life = 150 days)[a]
Ethoxylated C11 alcohol	Readily biodegradable (half-life = 15 days)[a]
2-Ethoxynaphthalene	Not readily biodegradable.
Ethylene glycol	Readily biodegradable (half-life = 15 days)[a]
Formic acid	Readily biodegradable (half-life = 15 days)[a]
Glutaraldehyde	Readily biodegradable (half-life = 15 days)[a]
Glycerol	Readily biodegradable (half-life = 15 days)[a]
Guar gum	Readily biodegradable (half-life = 15 days)[a]
Hemicellulase	Readily biodegradable (half-life = 15 days)[a]
1,6-hexanediol	Readily biodegradable (half-life = 15 days)[a]
Hydrochloric acid	Dissociates completely in aqueous media
Isopropanol	Readily biodegradable (half-life = 15 days)[a]
2-Mercaptoethyl alcohol	Readily biodegradable (half-life = 15 days)[a]
Methanol	Readily biodegradable (half-life = 15 days)[a]
N-benzyl-alkylpyridium chloride	No data.
Quat. Ammonium compds. Bis (hydrogenated tallow alkyl) dimethyl, salts with bentonite	Organic component: not readily biodegradable.
Pine oil	Readily biodegradable (half-life = 15 days)[a]
Polyoxyethylene nonylphenol ether	Readily biodegradable (half-life = 15 days)[a]
Polyoxyethylene-polyoxypropylene block copolymer	Not biodegradable.
Potassium chloride	Dissociates completely in aqueous media
Potassium hydroxide	Dissociates completely in aqueous media
Potassium persulfate	Dissociates completely in aqueous media
Potassium sorbate	Readily biodegradable (half-life = 15 days)[a]
2-Propenoic acid, homopolymer, ammonium salt	Not readily biodegradable
Sodium benzoate	Readily biodegradable (half-life = 15 days)[a]
Sodium bisulfite	Dissociates completely in aqueous media
Sodium erythrobate	Readily biodegradable (half-life = 15 days)[a]
Sodium hydroxide	Dissociates completely in aqueous media
Sodium polyacrylate	Not readily biodegradable
Sodium tetraborate decahydrate	Dissociates completely in aqueous media
Tar bases, quinoline deriv., benzyl chloride - Quat.	No data

Table 8 Exposure Assumptions - Cattle
Condor Energy Services Hydraulic Fracturing Fluid System

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/day	86
	EF	Exposure frequency	day/yr	15
	ED	Exposure duration	yr	8
	BW	Body weight	kg	454
	AT-NC	Averaging time - noncancer	days	2,920

Table 9 Exposure Assumptions - Kangaroo
Condor Energy Services Hydraulic Fracturing Fluid System

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/day	3
	EF	Exposure frequency	day/yr	10
	ED	Exposure duration	yr	15
	BW	Body weight	kg	25
	AT-NC	Averaging time - noncancer	days	5,475

Table 10 Exposure Assumptions - Dingo
Condor Energy Services Hydraulic Fracturing Fluid System

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/day	0.75
	EF	Exposure frequency	day/yr	10
	ED	Exposure duration	yr	15
	BW	Body weight	kg	13
	AT-NC	Averaging time - noncancer	days	5,475

Table 11
Condor Energy Services Hydraulic Fracturing Fluid System

ANZECC Water Quality Guideline (2000)

Constituent (CAS No.)	Substance	Freshwater Trigger Value
Alcohols, C9-11, ethoxylated (68439-46-3)	Alcohol ethoxylates	140 µg/L
Ethoxylated C11 alcohol (34398-01-1)	Alcohol ethoxylates	140 µg/L
Sodium tetraborate decahydrate (1303-96-4)	Boron	370 µg/L

$PNEC_{water}$ Values

Constituents	Endpoint	$E(L)C_{50}$ or NOEC (mg/L)	Assessment Factor	$PNEC_{water}$ (mg/L)
Acetic acid (64-19-7)	Acute fish or *Daphnia*	300.82	100	3.0
Acrylamide/sodium acrylate copolymer (25085-02-3)	Acute fish	100	1,000	0.1
Ammonium persulfate (7727-54-0)	Acute fish	76.3	100	0.8
Ammonium sulfate (7783-20-2)	Chronic fish	3.12	50	0.06
Amylase, alpha (9000-90-2)	Acute algae	5.2	100	0.05
Castor oil, ethoxylated (61791-12-6)	Acute fish	45	100	0.45
Choline chloride (67-48-1)	Chronic *Daphnia*	30	100	0.3
Cinnamaldehyde (104-55-2)	Acute fish	4.15	100	0.04
Diethylene glycol (111-46-6)	Chronic algae	2,700	100	27
Distillates (petroleum), hydrotreated light (64742-47-8)	-[a]	-	-	-
2-Ethyoxynaphthalene (93-18-5)	Acute algae	3.9	100	0.04
Ethylene glycol (107-21-1)	Acute fish	100	10	10
Formic acid	Acute fish	100	100	1

$PNEC_{water}$ Values

Constituents	Endpoint	E(L)C_{50} or NOEC (mg/L)	Assessment Factor	$PNEC_{water}$ (mg/L)
(64-18-6)				
Glutaraldehyde (111-30-8)	Chronic algae	0.025	10	0.0025
Glycerol (56-81-5)	Acute *Daphnia*	10,000	1,000	10
Guar gum (9000-30-0)	Acute *Daphnia*	6.2	1,000	0.006
Hemicellulase (9025-56-3)	Acute fish	52.1	100	0.5
1,6-Hexanediol (629-11-8)	Acute *Daphnia*	500	100	5
Hydrochloric acid (7647-01-0)	-[a]	-	-	-
Isopropanol (67-63-0)	Chronic *Daphnia*	30	100	0.3
2-Mercaptoethyl alcohol (60-24-2)	Chronic *Daphnia*	0.063	50	0.0013
Methanol (67-56-1)	Acute *Daphnia*	10,000	1,000	10
N-benzyl-alkylpyridium chloride (68909-18-2)	Acute algae	0.47	1,000	0.005
Quat. Ammonium compds, bis (hydrogenated tallow alkyl) dimethyl, salts with bentonite (68955-58-2)	Chronic *Daphnia*	3.2	50	0.06
Pine oil (8002-09-3)	Acute fish	18.4	1,000	0.02
Polyoxyethylene nonylphenol ether (9016-45-9)	Chronic *Daphnia*	0.285	50	0.006
Polyoxyethylene-polyoxypropylene block copolymer (9003-11-6)	Acute aquatic organisms	100	1,000	0.1
Potassium carbonate (584-08-7)	-[a]	-	-	-
Potassium chloride (7447-40-7)	Acute algae	100	1,000	0.1
Potassium hydroxide (1310-73-2)	-[a]	-	-	-
Potassium persulfate (7727-21-1)	Acute fish	76.3	100	0.8
Potassium sorbate (24634-61-5)	Chronic *Daphnia*	8.46	50	0.17
2-Propenoic acid,	Chronic *Daphnia*	12	10	1.2

$PNEC_{water}$ Values

Constituents	Endpoint	$E(L)C_{50}$ or NOEC (mg/L)	Assessment Factor	$PNEC_{water}$ (mg/L)
homopolymer, ammonium salt (9003-03-6)				
Sodium benzoate (532-32-1)	Acute algae	30.5	100	0.3
Sodium bisulfite (7631-90-5)	Chronic *Daphnia*	8.3	10	0.8
Sodium erythrobate (6381-77-7)	Acute fish, *Daphnia*, algae	100	100	1
Sodium hydroxide (1310-72-2)	-[a]	-	-	-
Sodium polyacrylate (9003-04-7)	Chronic *Daphnia*	12	10	1.2
Tar bases, quinoline deriv., benzyl chloride – Quat. (72480-70-7)	No data	-	-	-

[a]Not calculated.

Comments: 20# Borate XL system with Acid Spearhead
Santos Limited Pre Job Fairview Generic Condor Energy Servies Fluid System Disclosure

Total injected fluid volume (kilolitres):	**397.468**

Comprising of:		
Base fluid type (e.g. water)	**Litres**	**% of total volume**
Makeup Water	331180.513	83.323%

Proppant type (e.g. sand)	**Proppant size**	**Kilograms**	**Litres**	**% of total volume**
Sand	40/70	3401.361	1283.254	0.323%
Sand	20/40	141428.571	53357.701	13.424%

Any wet chemical constitutes:	**Litres**	**CAS Number**	**% of total volume**
Alcohols, C9-11, ethoxylated	49.613	68439-46-3	0.0125%
Ethoxylated C11 Alcohol	148.838	34398-01-1	0.0374%
Ethylene Glycol	0.378	107-21-1	0.0001%
Choline Chloride	26.082	67-48-1	0.0066%

Santos

Appendix C11
Halliburton Hybor and Delta Hydraulic Fracturing Fluid Systems

C1.0 Introduction

Santos Ltd. (Santos) is looking to use two Halliburton Hybor (DFS-BCG-H) and Delta (DFS-BGB) hydraulic fracturing fluid systems for development of coal seam gas (CSG) resources in the Surat and Bowen Basins of Queensland. The disclosures for the Haliburton Hybor and Delta hydraulic fracturing fluid systems, including a listing of the chemical constituents and percent of total volume in the fluid system, are provided in **Appendix C11-1**.

As presented in **Section 5.0** of the Hydraulic Fracturing Risk Assessment, Santos used a weight-of-evidence approach to evaluate the potential for human health and environmental (e.g., ecological) risks as a result of the hydraulic fracturing processes and the use of the Halliburton Hybor and Delta hydraulic fracturing fluid systems.

EHS Support, LLC (EHS Support) conducted a Quantitative Risk Assessment (QRA) to meet Conditions 49e and 49f of the 2 October 2011 approval under the *Environmental Protection and Biodiversity Conservation Act 1999* (EPBC 2008/4059) and the Environmental Amendment (EA) conditions to assess the toxicity of the mixtures.

The results and conclusions of the qualitative risk assessment components and the QRA are presented below. Refer to **Section 6.0** through **Section 8.0** for detailed discussions on the methodologies employed for the qualitative risk assessment and QRA components, which are referenced in the sections below.

C2.0 Qualitative Risk Assessment and Evaluation

C2.1 Chemicals Evaluated

The Halliburton Hybor ((DFS-BCG-H) and Delta (DFS-BGB) hydraulic fracturing fluid systems were assessed. The list of individual chemicals assessed is presented in **Table 1** below. A mass balance of the chemicals is provided as **Table C11-1a** and **Table C11-1b**.

Information regarding the chemical and physical properties of the individual chemicals listed below as well as the approximate percentage present in the hydraulic fracturing system can be found on the Safety Data Sheets in **Appendix E**.

The fluid system does not contain BTEX (benzene, toluene, ethylbenzene, xylenes) or polycyclic aromatic hydrocarbons (PAHs) based on EHS Support's understanding that Halliburton has tested all their products. Field monitoring will also be conducted in accordance with regulatory requirements. While none of the fracturing fluid chemicals identified contain BTEX or PAHs, PAHs occur naturally in coal and it is possible that certain PAHs may naturally be present in the coal seam groundwater used in the hydraulic fracturing process.

Table 1: Hydraulic fracturing chemicals

Chemical	CAS Number
Halliburton Hybor DFS-BCG-H Fluid System	
Acetic acid	64-19-7
Alcohols, C12-15, ethoxylated	68131-39-5
Amides, tall-oil fatty, N,N-bis(hydroxyethyl)	68155-20-4

Sodium Sulfate	7757-82-6
Tributyl tetradecyl phosphonium chloride	81741-28-8

C2.2 Risk Assessment Framework and Findings

As discussed in **Section 5.0**, a systematic weight of evidence approach was utilised to complete the risk assessment for the Halliburton Hybor and Delta hydraulic fracturing fluid systems. The work has involved the following evaluations:

Qualitative Assessment Methodologies

- PBT Assessment
- Exposure Assessment
- Mass Balance of Fluid System
- Fate and Transport Modelling

Quantitative Risk Assessment Methodologies

- Quantitative Human Health Risk Assessment (HHRA)
- Quantitative Ecological Risk Assessment for Terrestrial and Aquatic Receptors

C2.3 PBT Assessment

For the environmental hazard assessment, a PBT (persistence, bioaccumulative, toxicity) assessment was conducted in accordance with the guidance developed by DEWHA (2009), as presented in the RA Compendium. The PBT assessment is conducted because of specific concerns for substances that can

be shown to persist for long periods in the environment, to bioaccumulate in food chains, and can give rise to toxic effects after a longer time and over a greater spatial scale than chemicals without these properties. These effects may be difficult to detect at an early stage because of long-term exposures at normally low concentration levels and long life-cycles of species at the top of the food chain.

The PBT approach outlined in **Section 6.1** was undertaken to rank the hydraulic fracturing chemicals based on PBT potential. As a result of this assessment, no chemical constituents identified in the Halliburton Hybor and Detla hydraulic fracturing fluid systems were classified as a PBT chemical and are therefore not considered to be inherently hazardous. The results of the PBT Assessment are presented in **Table 2**, attached.

C2.3 Exposure Assessment

As discussed in **Section 7.0**, the exposure assessment identified receptors potentially exposed to chemicals of potential concern (COPCs) identified for the study and outlined the exposure pathways by which the receptors may come in to contact with the COPCs. A detailed exposure assessment was not conducted in the qualitative risk assessment.

C2.4 Mass Balance of Fluid System

A quantitative mass balance calculation was undertaken to identify the amount of each chemical additive of the hydraulic fracturing fluid systems. The results of the mass balance calculations are presented in **Table C11-1a** and **Table C11-1b**.

C2.5 Fate and Transport Modelling

As discussed in **Section 7.2**, fate and transport modelling was conducted on a range of key constituents of interest in typical hydraulic fracturing fluid systems. These results provided the framework for assessing potential mobility of all constituents used in hydraulic fracturing. The modelling demonstrated that despite the variability in chemical properties between fluid systems there is limited potential for chemicals to migrate within the coal seams. Refer to **Section 7.2** for further details.

C3.0 Quantitative Risk Assessment

In accordance with the methodologies presented in **Section 8.0**, a QRA was conducted on theoretical datasets for those chemicals identified in the Halliburton Hybor-Delta hydraulic fracturing fluid systems. The QRA approach evaluates the toxicity of the individual substances and characterises the cumulative risks of the total effluent toxicity and ecotoxicity.

Generally, this methodology includes the identification of the hazards posed by constituents in the flowback water, compilation of the toxicity criteria for each constituent, development of exposure models to estimate the daily intake of the constituents, and calculations of individual constituent hazard quotients (daily intake divided by the toxicity criteria) and a cumulative constituent hazard index (HI) for each potentially complete exposure pathway for each human or terrestrial receptor.

Potential complete exposure pathways to the storage of flowback from hydraulically stimulated wells, and potential risks to humans, terrestrial and aquatic receptors from the potential storage and accidental releases are evaluated in the QRA.

No further assessment of groundwater was determined to be necessary due to lack of potentially complete exposure pathways. Detailed operational procedures have been provided that are designed to contain the hydraulic fracturing fluids within the coal sequences, and no connection exists between groundwater in the coal seams and surface-water or springs (and therefore Matters of National Environmental Significance [MNES]). Further, the potential risks to workers involved with the hydraulic fracturing process were not considered as detailed Health and Safety (H&S) procedures are employed to manage exposures. The QRA considered the following specific exposure pathways:

1. Exposure of trespassers to flowback water contained within flowback storage ponds.
2. Exposure of terrestrial receptors (e.g., livestock and wildlife) to flowback water contained within the flowback storage tank.
3. Exposure of aquatic receptors to flowback water in the situation of an accidental release, such as from piping or a release from the flowback storage tank. These potential releases could include a failure of containment systems, overtopping of the dam or in an extreme situation (considered highly unlikely) structural failure of the dam itself.

C3.1 Exposure Assessment

The purpose of the exposure assessment in the QRA was to predict the magnitude and frequency of potential human exposure to each COPC following the methodologies presented in **Section 8.1**. A conceptual site model (CSM) was developed which describes the potential receptors and exposure scenarios for the flowback water used in this exposure assessment. The potential exposures to receptors were evaluated based on the potential for a complete exposure pathway.

As discussed in **Section 8.2**, exposure point concentrations (EPCs) were derived for the theoretical assessment; empirical data were not available for evaluation. The EPCs for the theoretical assessment were calculated by estimating the mass and discharge flow of the COPCs in the flowback water.

C3.2 Human Health QRA

A human health hazard assessment was conducted according to the methodologies presented in **Section 8.4**. The purpose of the hazard assessment process was to summarise the environmental data, and to address the toxicological assessment of the COPCs that will be evaluated further in the risk assessment process.

Exposure assumptions for the human trespasser scenario were developed based on default or site-specific assumptions (**Section 8.4**). This receptor exposure pathway includes a small child to teenager

that may come in contact with the above grade water exposure scenario for approximately 20 days/year for a 10-year period with potential incidental ingestion [of 50 millilitres (ML) of water] and dermal contact (e.g., swimming where the whole body gets wet) for one-half hour. The exposure parameters used in the QRA are presented on **Table 3**, attached.

Calculation of intake of COPCs was performed using the equations presented below:

Ingestion of water:

$$Intake\ (mg/kg-day)\ =\ (CW\ x\ IR\ X\ EF\ X\ ED)\ /\ (BW\ x\ AT)$$

Dermal contact with water:

$$Absorbed\ dose\ (mg/kg-day)\ =\ (CW\ x\ SA\ x\ DP\ x\ ET\ x\ EF\ x\ ED\ x\ CF)\ /\ (BW\ x\ AT)$$

Where:

AT = averaging time (days)
BW = body weight (kg)
CF = correction factor (1 x 10-3 l/cm3)
CW = concentration in water (mg/l)
DP = dermal permeability factor (Kp – cm/hr).
ED = exposure duration (years)
EF = exposure frequency (day/year)
ET = exposure time (hr/day or hours/hours)
IR = ingestion rate (l/hr)
SA = skin surface area available for contact (cm2/d)

C3.3 Toxicity Assessment

A toxicity assessment was conducted to determine the relationship between the dose of a COPC taken into the body, and the probability that an adverse effect will result from that dose. Quantitative estimates of the potency of COPCs include two sets of toxicity values, one for genotoxic carcinogens and one for other non-genotoxic carcinogens and non-carcinogenic effects. As discussed in **Section 8.4**, detailed toxicological profiles were developed for the chemicals. The toxicological profiles are included in the risk dossiers in **Appendix F11**.

The assessment of toxicity of the COPCs was used to develop initial screening criteria for human health exposure scenarios as discussed in **Section 8.4**. The derivation of Oral Reference Dose and Drinking Water Guideline Values are presented in **Table 4**, attached. Australian Drinking Water Screening Values for the COPCs are also presented on **Table 4**, attached.

C3.4 Exposure Point Concentration

As presented above, the exposure scenarios are based on anticipated conditions, and the potential for exposure to the theoretical estimate of exposure. EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations and the existing environmental conditions within the fracturing fluids flowback storage ponds, and the flowback used in the irrigation fields.

To assess the potential flux of hydraulic fracturing chemicals to the environment, vendor disclosures for the hydraulic fracturing fluid systems were reviewed, and the chemical concentrations of key inputs were determined.

For the theoretical calculations, the mass and estimated chemical concentrations of the COPCs in the Halliburton Hybor and Delta hydraulic fracturing fluid systems, as presented in **Table C11-1a** and **Table C11-1b**, were used to estimate the potential concentrations in water within the fracturing fluids sump or flare pit, or flowback storage ponds. Based on stimulation flow back monitoring conducted by Santos and the QRA completed for the Schlumberger Fluid Systems (**Appendix C**), 20 percent (%) of the total mass of constituents injected is assumed to be recovered in the flowback water. This mass is diluted within 150 % of the injected volume (the minimum volume that must be flowed back) to establish an "estimated" concentration (i.e., concentration expected due to full dilution of the back-flow water) within the flowback storage ponds.

The flowback water will be contained within the flowback storage ponds for a projected maximum period of one year of operational activity before transfer or conveyance to the water treatment facilities and or transferred into Santos water conveyance systems (for treatment) and thereby blended with other conveyance systems water not containing these constituents. To be conservative it has been assumed that the fluids are stored with ponds with the concentration of COPCs in the flowback storage pond water adjusted, where applicable, to account for the biodegradation and photolytic degradation of constituents over time. The biodegradation information was obtained from the Organisation for Economic Cooperation and Development (OECD) ready tests (OECD, 1992) that were developed as a first-tier testing scheme to provide preliminary screening of organic chemicals. The ready tests are stringent screening tests that are conducted under aerobic conditions in which a high concentration of the test substance is used, and biodegradation is measured by non-specific parameters including dissolved organic carbon, biochemical oxygen demand and carbon dioxide production. **Table 5**, attached, presents the environmental fate information that was used to assess biodegradation of COPCs, and that was applied at the time periods of 0, 30, 150 and 300 days from initial flowback.

The water quality data derived using these assumptions for the theoretical COPCs are presented in **Table C11-1a and Table C11-1b**.

The theoretical EPCs for the four exposure time periods (0, 30, 150 and 300 days) were compared to human health toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C11-2a** and **Table C11-2b**.

C3.5 Risk Estimation

Risk estimation was performed in accordance with the methodologies outlined in **Section 8.4**. The total target risk range for carcinogens was 1×10^{-4} to 1×10^{-6}; the target HI for non-threshold effects is less than or equal to 1.0.

The results of the theoretical assessments for Halliburton Hybor and Delta hydraulic fracturing fluid systems for the trespasser exposure scenarios (day 0 and day 150, Halliburton Hybor and Delta hydraulic fracturing fluid system events) are summarized in **Tables 6a, 6b, 7a and 7b,** attached. As discussed above, the theoretical assessment was conducted at the well pad sites.

The exposure scenarios include the Halliburton hydraulic fracturing fluid system event, as presented in **Table C11-1a** and **Table C11-1b** for day 0 and day 150 from the flowback storage tank. On day 0, the trespasser had risks above the target of 1.0 for the Hybor (DFS-BCG-H) hydraulic fracturing fluid system (HI=22, **Table 6a**, attached); the risks for the Delta (DFS-BGB) were below the target at a HI of 0.36 (**Table 6b**, attached). The elevated HI for the DFS-BCG-H were due to the ingestion exposure pathway of chlorous acid, sodium salt and diethanolamine. The risks for the trespasser on day 150 were less than the target HI of 1.0 for both the Hybor (DFS-BCG-H) hydraulic fracturing fluid system (HI=0.2, **Table 7a**, attached) and Delta (DFS-BGB) hydraulic fracturing fluid system (0.12, **Table 7b**, attached).

The potential exposures resulting in any unacceptable risks discussed above are subject to management and operational controls that can be implemented to control potential exposures. Additionally, the QRA used very conservative exposure assumptions.

C3.6 Ecological Risk Assessment

As discussed in **Section 8.5**, a screening level ecological risk assessment (ERA) was conducted to evaluate the potential for adverse ecological effects to terrestrial and aquatic ecological receptors that may be exposed to residual levels of hydraulic fracturing fluids in surface water used in the CSG fields.

C3.7 Exposure Assessment

Terrestrial receptors evaluated in the ERA include domesticated livestock, large mammalian wildlife and small mammalian wildlife. Beef cattle were used to evaluate domesticated livestock, kangaroos evaluated for large mammalian wildlife, and dingos for small mammalian wildlife. Aquatic receptors evaluated included invertebrates and fishes.

The estimate for dose-based or intake rates for the assessment endpoints for wildlife representing domestic livestock and native mammalian species used the following general equation:

TI = Cwater x IRwater x EF x ED / BW x ED x 365 days/year

Where:

TI = Total intake of COPC (mg/kg/day)

Cwater = Concentration of COPC in water (mg/l)

IRwater = Ingestion rate (litres/day)

EF = Exposure frequency (days/year)

ED = Exposure duration (years)

BW = Body weight (kg)

The exposure assumptions are presented in **Tables 8** through **10**, attached.

C3.8 Toxicity Assessment

To evaluate the potential for adverse ecological effects, toxicity reference values (TRVs) are selected as measurement endpoints for the ERA that will be used in the risk analysis. The TRVs are based on COPC levels that imply no adverse effects or levels that represent the lowest concentration at which adverse effects may occur. The ERA used two types of TRVs (**Section 8.5.3**). The first TRV is a concentration-based TRV to evaluate the concentration of the selected COPC in the surface water and direct exposure by the aquatic ecological receptor. The determination of TRVs for freshwater was conducted according to the predicted no-effects concentration (PNEC) guidance in the Environmental Risk Assessment Guidance Manual for Industrial Chemicals prepared by the Australian Environmental Agency (AEA, 2009). As discussed in **Section 8.4**, detailed environmental profiles were developed for the chemicals. The environmental profiles are included in the risk dossiers in **Appendix G11**. **Table 11**, attached, presents the COPC, the endpoint, NOEC [milligrams per litre (mg/L)], assessment factor, and the aquatic PNEC (mg/L). The second TRV is a dose-based TRV to evaluate the intake dose of the selected COPC from exposure to surface water by ingestion. The calculated TRVs for each of the mammalian ecological receptors evaluated in the ERA are presented in the species-specific ecological risk models.

C3.9 Exposure Point Concentration

EPCs for the exposure assessment were calculated using the results of theoretical fate and transport modelling calculations. The potentially affected flowback water that represents complete exposure pathways for the ecological receptors includes the surface water systems (e.g., flowback storage ponds and mud pits) that were used to estimate the EPCs for the human health receptors. The EPCs for the ecological receptors were estimated assuming the same Scenarios, with exposure occurring in the irrigation area where irrigation water may pool and wildlife may drink from the standing water. **Table C11-1a** and **Table C11-1b** presents the calculated EPCs for the ecological receptor exposure scenarios. The theoretical EPCs for the four exposure time periods (0, 30, 150, and 300 days) were compared to ecological based toxicity-based screening levels, and the results of this comparison, including the ratio of exceedance of screening levels, is presented in **Table C11-3a** and **Table C11-3b**.

Risks were characterised in accordance with the methodologies discussed in **Section 8.5.6**. The resulting ecological hazard quotient must be less than or equal to 1.0 for risks to be considered acceptable.

C3.10 Estimation of Risk

The HI calculated for flowback water for aquatic risk were elevated above the acceptable level for the majority of COPCs evaluated (**Table C11-3a** and **Table C11-3b**). Where large discharges of flowback water occur to surface water and/or flux dilution within the surface-water was insufficient, potential impacts on aquatic receptors could occur. As noted in the toxicity assessment section above, the lack of a robust aquatic toxicological database resulted in highly conservative aquatic screening values for the theoretical exposure scenario COPCs to be conservatively very low.

The results of the theoretical assessments for Halliburton hydraulic fracturing fluid system for the livestock cattle, kangaroo and dingo are summarized in **Tables 12a through 17b**, attached. The exposure scenarios include the Halliburton hydraulic fracturing fluid systems EPCs presented in **Table C11-1a** and **Table C11-1b** for day 0 and day 150 from the fracturing fluid well flowback. The modelled risks from Hybor (DFS-BCG-H) hydraulic fracturing fluid system chemicals in the flowback water were above the target of 1.0 for the cattle (HI=12, **Table 12a**, attached); the calculated risks were less than the target for the Delta (DFS-BGB) hydraulic fracturing fluid system (HI = 0.64, **Table 12b**, attached). The HI were acceptable for the modelled values for day 150 for both the Hybor (DFS-BCG-H; HI = 0.0053, **Table 13a**, attached) and Delta (DFS-BGB; HI = 0.00073, **Table 13b**, attached) hydraulic fracturing fluid systems.

The modelled risks for the kangaroo for the day 0 release scenario slightly exceeded the target of 1.0 for the DFS-BCG-H (HI = 2.5, **Table 14a**, attached); however, the risks for the Delta (DFS-BGB) hydraulic fracturing fluid system was less than 1.0 (HI = 0.13, **Table 14b**, attached). The modelled risks for day 150 for the kangaroo for both fluid systems did not exceed the target of 1.0: HI for Hybor (DFS-BCG-H) hydraulic fracturing fluid was 0.15 (**Table 15a**, attached); HI for Delta (DFS-BGB) hydraulic fracturing fluid system was 0.02 (**Table 15b**, attached).

For the dingo, the modelled risks for the day 0 and day 150 scenarios for both hydraulic fracturing fluid systems did not exceed the target of 1.0. The modelled HIs ranged from 1.0 to 0.054 for day 0 (**Table 16a,** and **16b**, attached) and from 0.06 to 0.0081 for day 150 (**Table 17a,** and **17b**, attached).

C4.0 Summary of QRA Findings

The QRA was completed as discussed in **Section 8.0**. An assessment was conducted using highly conservative theoretical calculations based on the chemicals utilised by Schlumberger in hydraulic fracturing. This assessment assumed that a range of theoretical concentrations of injected chemicals would be present in the flowback water based on biodegradation rates, where applicable.

Consistent with the risk assessment and groundwater fate and transport modelling conducted by Golder, no potentially complete exposure pathways were identified for groundwater. Potential exposures are limited to the aboveground storage and handling of flowback water as part of the CSG Water Management Plan (WMP). Management of CSG water involves the temporary storage of flowback water in flowback storage ponds.

The exposure scenario modelled for the QRA was a trespasser being exposed to flowback water under various EPC scenarios. Based on quantitative risk calculations, the potential risks for the trespasser were unacceptable for the EPC scenarios for the Hybor (DFS-BCG-H) hydraulic fracturing fluid system in day 0, but were significantly reduced to potential risks only exceeding the HI target of 1.0 in the day 150 scenario as a result of biodegradation of the risk drivers. The modelled risks for the Delta (DFS-BGB) hydraulic fracturing fluid system were acceptable for both the day 0 and day 150 scenarios for the trespasser. The potential exposures resulting in any unacceptable risks discussed above are subject to management and operational controls that can be implemented to control potential exposures. Additionally, the QRA used very conservative exposure assumptions. There were no carcinogenic risks identified.

The modelled risks from Halliburton Hybor (DFS-BCG-H) hydraulic fracturing fluid system chemicals in the flowback water were unacceptable for the livestock cattle and kangaroo on day 0, but were acceptable for the dingo on day 0 and all receptors on day 150. The modelled risks for the Halliburton Delta (DFS-BGB) hydraulic fracturing fluid system chemicals in flowback water were acceptable for the cattle, kangaroo, and dingo for both day 0 and day 150 scenarios. The potential exposures resulting in any unacceptable risks discussed above are subject to management and operational controls that can be implemented to control potential exposures. Similarly, potential impacts could occur if releases of flowback water were to occur to aquatic environments. Based on the use of low permeability materials (clay liners) and operational controls that limit the potential for turkey nest and dam overflows, the potential for these risks are also considered limited.

A combination of management and operational controls are being implemented to eliminate and control the potential for exposures. These include:

- Worker training and hazard identification
- Use of appropriate personal protective equipment (gloves, etc.)
- Flowback storage pond fencing to prevent entry of livestock and native fauna and minimise trespassing
- Use of low permeability materials or dam liners and routine dam inspections to prevent releases from flowback storage ponds
- Routine operational and security patrols to prevent trespassing

C5.0 Conclusions

A weight-of-evidence evaluation of potential risks as described in **Section 5.0** was performed for the Halliburton Hybor (DFS-BCG-H) and Delta (DFS-BGB) hydraulic fracturing fluid system. Based on the qualitative and quantitative risk characterisations, the overall risk to human health and the environment modelled were unacceptable for day 0 but were significantly reduced to potential risks not exceeding the HI target of 1.0 in day 150 scenario as a result of biodegradation of the risk drivers. Existing operational control activities employed by Santos are in place that will limit the potential risks to human health and the environment. These measures include:

- Occupational health and safety procedures implemented during hydraulic fracturing operations to prevent workers from making direct contact with chemicals during spills and when handling flowback water or sediments
- Environmental authority conditions that preclude the construction of well pads within 100 metres of a watercourse of water body
- Implementation of spill containment procedures during operations to prevent migration of and exposure to chemicals
- Disposal or capping of sediments contained within drained mud pits and turkey nests, to prevent exposure to contaminates in windborne dust
- Fencing of drill pads to prevent trespassers from entering and installation of signs to indicate that the water in the turkey nests and mud pit is not potable and may contain contaminants
- Installation and maintenance of fences around the well pad to prevent access to the drill pad by livestock and large native fauna
- Santos operational procedures to ensure well integrity and design of fracture to stay within the target seam
- Mud pits and turkey nests with clay liners, or similar material, to prevent seepage of flowback water into underlying aquifers

Monitoring of water supply bores and surface water for a representative suite of chemicals within 2 kilometres of the wells (and 200 m vertical separation) that are fractured will be conducted (as needed) to confirm the conclusion of incomplete exposure pathways and low risk.

No additional risks, other than those previously discussed, were identified with the chemicals or systems employed in hydraulic fracturing. Evaluation of other potential risks associated with hydraulic fracturing (i.e., noise and vibration) was conducted. Refer to **Section 9.0** for methodology specifics and results of this evaluation.

Table 8 Exposure Assumptions - Cattle
Halliburton Hybor (DFS-BCG-H) and Delta (DFS-BGB) Hydraulic Fracturing Fluid Systems

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/day	86
	EF	Exposure frequency	day/yr	15
	ED	Exposure duration	yr	8
	BW	Body weight	kg	454
	AT-NC	Averaging time - noncancer	days	2,920

day/yr = days per year
kg = kilograms
l/day = litres per day
yr = year

Table 9 Exposure Assumptions - Kangaroo
Halliburton Hybor (DFS-BCG-H) and Delta (DFS-BGB) Hydraulic Fracturing Fluid Systems

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/day	3
	EF	Exposure frequency	day/yr	10
	ED	Exposure duration	yr	15
	BW	Body weight	kg	25
	AT-NC	Averaging time - noncancer	days	5,475

day/yr = days per year
kg = kilograms
l/day = litres per day
yr = year

Table 10 Exposure Assumptions - Dingo
Halliburton Hybor (DFS-BCG-H) and Delta (DFS-BGB) Hydraulic Fracturing Fluid Systems

Exposure Route	Parameter Code	Parameter Definition	Units	Parameter Value
Ingestion	IR	Ingestion rate	l/day	0.75
	EF	Exposure frequency	day/yr	10
	ED	Exposure duration	yr	15
	BW	Body weight	kg	13
	AT-NC	Averaging time - noncancer	days	5,475

day/yr = days per year
kg = kilograms
l/day = litres per day
yr = year

Table 11 ANZECC Water Quality and PNEC Values
Halliburton Hybor (DFS-BCG-H) and Delta (DFS-BGB) Hydraulic Fracturing Fluid Systems

ANZECC Water Quality Guidelines		
Constituent (CAS No.)	**Substance**	**Freshwater Trigger Value**
Alcohols, C12-15, ethoxylated (68131-39-5)	Alcohol ethoxylates	140 µg/L
Disodium octaborate tetrahydrate (12008-41-2)	Boron	370 µg/L

PNEC Values				
Constituents	**Endpoint**	**E(L)C_{50} or NOEC (mg/L)**	**Assessment Factor**	**$PNEC_{water}$**
Acetic acid (64-19-7)	Acute fish or *Daphnia*	300.82	100	3
Amides, tall oil fatty, N,N-bis(hydroxyethyl) (68155-20-4)	Chronic *Daphnia*	0.07	10	0.007
Butyl alcohol (71-36-3)	Chronic Daphnia	4.1	50	0.08
Cellulase enzyme (9012-54-8)	Acute fish	52.1	1000	0.05
Chlorous acid, sodium salt (7758-19-2)	Acute algae	1	1,000	0.001
Choline chloride (67-48-1)	Chronic *Daphnia*	30	100	0.3
Citric acid (77-92-9)	Acute Daphnia	440	1,000	0.44
Coffee Extract (68916-18-7)	Acute fish, invertebrates, or algae	100 [WAF]	100	1 [WAF]
Crystalline silica (14808-60-7)	[a]	-	-	-
Diethanolamine (111-42-2)	Chronic algae	1.1	50	0.02
Ethanol (64-17-5)	Chronic *Daphnia*	9.6	10	1
Ethylene glycol (107-21-1)	Acute fish	100	10	10
Fatty acids, tall oil, ethoxylated (61791-00-2)	Acute *Daphnia*	12.41 [WAF]	100	0.12 [WAF]

Table 11 ANZECC Water Quality and PNEC Values
Halliburton Hybor (DFS-BCG-H) and Delta (DFS-BGB) Hydraulic Fracturing Fluid Systems

PNEC Values				
Constituents	**Endpoint**	**E(L)C_{50} or NOEC (mg/L)**	**Assessment Factor**	**$PNEC_{water}$**
Sodium sulfate (7757-82-6)	Chronic *Ceriodaphnia*	1109	100	11
Tributyl tetradecyl phosphonium chloride (81741-28-8)	Acute algae	0.019	1,000	1.9×10^{-5}
Triethanolamine (102-71-6)	Chronic *Daphnia*	16	50	0.32
Ulexite (1319-33-1)	[a]	-	-	-

[a]Not calculated.
[b]Based on QSAR model, PETRORISK v.7.04.
*Read-across from hydrocarbons, C12-C15, n-alkanes, isoalkanes, cyclics, <2% aromatics (CAS No. 869062-45-3).
ANZECC = Australian and New Zealand Environment and Conservation Council
CAS = Chemical Abstracts Service
E(L)C_{50} = effects (lethal) concentration at 50 percent total effect/lethality
mg/L = millgrams per litre
NOEC = no observed effect concentration
PNEC = predicted no-effect concentration
QSAR = quantitative structure - activity relationship
WAF = Water Accommodated Fraction
µg/L = micrograms per litre

APPENDIX D TIERED FRAMEWORK

APPENDIX D.1 SCREENING FRAMEWORK

Criteria	Tier 1	Tier 2	Tier 3	Tier 4	Tier 5
General PBT Assessment Step					
Combined PBT Assessment Category	Not a PBT	Not a PBT	Not a PBT	Identified as a PBT	N/A
Chemical Databases of Concern Assessment Step					
Listed as a chemical of concern on relevant databases	Not listed as a chemical of potential concern on the following databases: - European Union Substance of Very High Concern (EU SVHC). - US National Toxicology Program (US NTP) Report on Carcinogens or International Agency Research on Cancer (IARC) Monographs. - European Commission Endocrine Disruptors Strategy - list of Category 1 substances with endocrine disrupting capacity. - Chemical Substances Control Law of Japan (CSCL) Class I and II Specified Chemical.	Not listed as a chemical of potential concern on the following databases: - European Union Substance of Very High Concern (EU SVHC). - US National Toxicology Program (US NTP) Report on Carcinogens or International Agency Research on Cancer (IARC) Monographs. - European Commission Endocrine Disruptors Strategy - list of Category 1 substances with endocrine disrupting capacity. - Chemical Substances Control Law of Japan (CSCL) Class I and II Specified Chemical.	Listed as a chemical of concern on the following databases: - European Union Substance of Very High Concern (EU SVHC). - US National Toxicology Program (US NTP) Report on Carcinogens or International Agency Research on Cancer (IARC) Monographs. - European Commission Endocrine Disruptors Strategy - list of Category 1 substances with endocrine disrupting capacity. - Chemical Substances Control Law of Japan (CSCL) Class I and II Specified Chemical.	Listed as a chemical of concern on the following databases: - European Union Substance of Very High Concern (EU SVHC). - US National Toxicology Program (US NTP) Report on Carcinogens or International Agency Research on Cancer (IARC) Monographs. - European Commission Endocrine Disruptors Strategy - list of Category 1 substances with endocrine disrupting capacity. - Chemical Substances Control Law of Japan (CSCL) Class I and II Specified Chemical.	Chemicals noted in the Rotterdam Accord including: - octabromodiphenyl ether - pentabromodiphenyl ether - perfluorooctane sulfonic acid - perfluorooctane sulfonates - perfluorooctane sulfonamides - perfluorooctane sulfonyls - polybromated biphenyls - short chain chlorinated paraffins - tetramethyl lead - tributyl tin compounds Chemicals restricted in the State of Queensland including: - Benzene* - Toluene* - Ethylbenzene* - m-&p- and o-Xylene*
Identified as Polymer of Low Concern	Yes (no further assessment required)	No	No	No	N/A
Persistence Assessment Step					
Persistence	Not persistent as defined by: Air - Half life < 2 days Water - Half life < 60 days Soil and Sediment - Half life < 6 months	Not persistent as defined by: Air - Half life < 2 days Water - Half life < 60 days Soil and Sediment - Half life < 6 months	Persistent as defined by: Air - Half life ≥ 2 days Water - Half life ≥ 60 days Soil and Sediment - Half life ≥ 6 months	Persistent as defined by: Air - Half life ≥ 2 days Water - Half life ≥ 60 days Soil and Sediment - Half life ≥ 6 months	N/A
Other Persistence Concerns – Chemical identified as potentially accumulating in soil and posing risks	No potential concerns with accumulation in soil and impacts on flora and fauna	No potential concerns with accumulation in soil and impacts on flora and fauna	Potential concerns with accumulation in soils based on ANZECC assessment b (for example metals such as Cd)	Potential concerns with accumulation in soils based on ANZECC assessment b (for example metals such as Cd)	N/A
Bioaccumulative Assessment Step					
Bioaccumulative	Does not Bioaccumulate as defined by: - Aquatic - BAF < 2000 or BCF < 2000 or log KoW < 4.2 (if BAF and BCF are not available) -Terrestrial - log Koa < 6 and log Kow < 2 - Food Chain Bioaccumulation Potential - BMF < 1	Does not Bioaccumulate as defined by: - Aquatic - BAF < 2000 or BCF < 2000 or log KoW < 4.2 (if BAF and BCF are not available) -Terrestrial - log Koa < 6 and log Kow < 2 - Food Chain Bioaccumulation Potential - BMF < 1	Does not Bioaccumulate as defined by: - Aquatic - BAF < 2000 or BCF < 2000 or log KoW < 4.2 (if BAF and BCF are not available) -Terrestrial - log Koa < 6 and log Kow < 2 - Food Chain Bioaccumulation Potential - BMF < 1	Does Bioaccumulate as defined by: - Aquatic - BAF ≥ 2000 or BCF ≥ 2000 or log KoW ≥ 4.2 (if BAF and BCF are not available) -Terrestrial - log Koa ≥ 6 and log Kow ≥ 2 - Food Chain Bioaccumulation Potential - BMF > 1	N/A
Toxicity Assessment Step					
Toxicity	Acute Toxicity: Fish -96h LC 50 >10 mg/L Invertebrates - 48h EC50 > 10 mg/L Algae and other aquatic plants -72 or 96h ErC50 > 10 mg/L	Acute Toxicity: Fish -96h LC 50 >1 to < 10 mg/L Invertebrates - 48h EC50 >1 to < 10 mg/L Algae and other aquatic plants -72 or 96h ErC50 >1 to < 10 mg/L	Acute Toxicity: Fish -96h LC 50 ≤ 1 mg/L Invertebrates - 48h EC50 ≤ 1 mg/L Algae and other aquatic plants -72 or 96h ErC50 ≤ 1 mg/L	Acute Toxicity: Fish -96h LC 50 ≤ 1 mg/L Invertebrates - 48h EC50 ≤ 1 mg/L Algae and other aquatic plants -72 or 96h ErC50 ≤ 1 mg/L	N/A
	Chronic Toxicity: Fish NOEC or Ecx >1 mg/L Invertebrates NOEC or Ecx > 1 mg/L Algae and other aquatic plants -NOEC or Ecx > 1 mg/L	Chronic Toxicity: Fish NOEC or Ecx >0.1 to < 1 mg/L Invertebrates NOEC or Ecx >0.1 to < 1 mg/L Algae and other aquatic plants - NOEC or Ecx >0.1 to < 1 mg/L	Chronic Toxicity: Fish NOEC or Ecx ≤ 0.1 mg/L Invertebrates NOEC or Ecx ≤ 0.1 mg/L Algae and other aquatic plants - NOEC or Ecx ≤ 0.1 mg/L	Chronic Toxicity: Fish NOEC or Ecx ≤ 0.1 mg/L Invertebrates NOEC or Ecx ≤ 0.1 mg/L Algae and other aquatic plants -NOEC or Ecx ≤ 0.1 mg/L	N/A
Risk Assessment Actions Required					
Risk Assessment Action Required	Hazard Assessment only. Do screening only and note it meets the above criteria. Develop toxicological profile	Hazard Assessment and Qualitative Assessment Only. Do screening only and note it meets the above criteria. Develop toxicological profile and PNECs for water and soil and provide qualitative discussion of risk	Quantitative Risk Assessment: Complete PBT, qualitative and quantitative assessment of risk. Quantitative assessment of risk will consider only Tier 3 chemicals in end use determination.	Quantitative Risk Assessment and Full Life Cycle Assessment Need to demonstrate that the chemical cannot be substituted. If r etained will need to conduct a full life cycle quantitative risk assessment including food chain risk assessment.	Banned from Use on Project. Would require specific assessment process and require extensive consultation prior to assessment.

** Above levels prescribed in the Queensland Environment Protection Regulation 1999*

APPENDIX E GOLDER SUPPORTING CHEMICAL-SPECIFIC PROPERTY INFORMATION

Santos

APPENDIX E.1 SCHLUMBERGER GUAR BASED SYSTEMS

Name	2-Methyl-4-Isothiazolin-3-one
Synonyms	2-Methyl-3(2H)-isothiazolone
CAS number	2682-20-4
Molecular formula	$C_4 H_5 N_1 O_1 S_1$
Product name	M275

Physical Properties	Value	Reference
Phase/state	NA	
Molecular weight	115.15 g/mol	EPISUITE
Melting point	47.48 ^{o}C	EPISUITE
Boiling point	237.75 ^{o}C	EPISUITE
Density/ specific gravity	NA	
Vapour pressure	0.031 mm Hg at 25^{o}C	EPISUITE
Solubility	5.367 x 10^{5} mg/L	EPISUITE
Henrys law constant	4.96 x 10^{-8} atm m^3/mole (BOND Method)	EPISUITE
Organic carbon partition coefficient (koc)	12.08 (MCI Method)	EPISUITE
Log organic carbon partition coefficient (log Koc)	1.082 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	-0.83	EPISUITE

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	NA	
Aerobic BOD	NA	
Anaerobic BOD	NA	
Biowin7 (Anerobic linear model)	Biodegrades fast	EPISUITE
Fugacity		
Air %	0.519	EPISUITE
Water %	34.1	EPISUITE
Soil %	65.3	EPISUITE
Sediment %	0.0797	EPISUITE
Bioconcentration factor (BCF)	3.162 L/kg wet wt	EPISUITE
Biotransformation half-life	0.02263 days	EPISUITE

Name	Boric Acid
Synonyms	Orthoboric acid, boron trihydroxide, trihydroxyborane
CAS number	10043-35-3
Molecular formula	H_3Bo_3
Product name	Crosslinker L10

Physical Properties	Value	Reference
Phase/state	Colourless, transparent crystals or white granules or powder.	HSDB, 2011
Molecular weight	61.833 g/mol	HSDB, 2011
Melting point	170.9^{o}C	HSDB, 2011
Boiling point	300 ^{o}C	IUCLID, 2000
Solubility	4.72% at 20 ^{o}C	HSDB, 2011
	5 x 10^4 g/m^3 at 25^{o}C	HSDB, 2011
	One gram dissolves in 18ml cold water or 4ml boiling water	Merck, 1996

Other Relevant Factors	Value	Reference
Reactivity		
Species & Reaction type	Incompatible /with/ alkali carbonates and hydroxides.	HSDB, 2011
pH	pH at 20 ^{o}C 6.1 (0.1% solution); 5.1 (1.0% solution); 3.7 (4.5% solution)	HSDB, 2011

Notes: 1 EPI Suite™ v4.0, United States Environmental Protection Agency.

NA - not available

Boron is found in the environment primarily combined with oxygen in compounds called borates. Common borate compounds include boric acid, sodium tetraborates and boron oxide (ATSDR, 2010). In water the dominant form of boron is boric acid, which does not dissociate readily (ADWG, 2004). As little information is available relating to guidelines for boric acid, guidelines for boron have been utilised as a surrogate. This is based on the assumption that boron guidelines account for boric acid as one of the constituents for boron.

Aquatic toxicity guidelines				
Guideline	**Year**	**Type**	**Value (g/m^3)**	**Notes**
ANZECC	2000	Aquatic toxicity	90 ug/L	Boron used as surrogate for boric acid.
USEPA	2006	Aquatic toxicity	NA	
Other water quality guidelines				
Guideline	**Year**	**Type**	**Value (g/m^3)**	**Notes**
ADWG	2004	Drinking water	4 mg/L	Boron used as surrogate for boric acid.
NZDWS	2008	Drinking water	1.4 mg/L	Boron used as surrogate for boric acid.
WHO	2006	Drinking water	0.3 mg/L	Boron used as surrogate for boric acid.
USEPA	2010	Human Health	16,000 mg/kg	Protective of residential soil. Boron used as surrogate for boric acid.
			23 mg/kg.	Protective of groundwater. Boron used as surrogate for boric acid.
IARC	2006	Carcinogen risk	NA	Boric acid and boron not listed in the IARC database.
ANZECC	2000	Stock water	0.5 mg/L	Boron used as surrogate for boric acid.

Aquatic Ecotoxicological Data

Chronic toxicity data							
Species name	**Common name**	**Endpoint**	**Effect**	**Effect measure**	**Test time (days)**	**Conc (%)**	**Reference**
Dicentrarchus labrax**	Sea Bass	LOEL	GRO	GAIN	60	10% v/v	ECOTOX

Note: ECOTOX data is for silica (CASRN 7631-86-9). There were several ECOTOX database entries for this compound and all were in the saltwater environment. Only one entry related to the endpoints considered in this report (mortality, growth, reproduction). This entry is provided in the Table above. The concentration units were reported as 10% v/v, which equates to 100,000 mg/L.

Media Type : sea water

GRO: Growth

GAIN: Weight gain

Name	Ethanol
Synonyms	Ethyl Alcohol, ethyl hydrate, ethyl hydroxide.
CAS number	64-17-5
Molecular formula	C_2H_6O
Product name	F104

Physical Properties	Value	Reference
Phase/state	Clear, colourless, very mobile liquid	HSDB, 2011
Molecular weight	46.07 g/mol	HSDB, 2011
Melting point	-114.1 ^{o}C	HSDB, 2011
Boiling point	78.5 ^{o}C	HSDB, 2011
Density/ specific gravity	0.789 at 20^{o}C	HSDB, 2011
Vapour pressure	59.3 mm Hg at 25^{o}C	HSDB, 2011
Solubility	Miscible in water	HSDB, 2011
	7.921 x 10^{5} mg/L at 25^{o}C	EPISUITE
Henrys law constant	5 x 10^{-6} atm m^{3}/mole	HSDB, 2011
Organic carbon partition coefficient (Koc)	1	HSDB, 2011
Log organic carbon partition coefficient (log Koc)	0.019 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	-0.31	HSDB, 2011

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	Biodegradation is expected to occur rapidly in the environment, unlikely to be persistent in the environment. Not expected to adsorb to suspended solids and sediment.	HSDB, 2011
Aerobic BOD	74% BOD in 5 days	HSDB, 2011
Anaerobic BOD	1.5 days under denitrifying conditions, 5 days under iron - reducing conditions.	HSDB, 2011
Biowin7 (Anaerobic Model Prediction)	Biodegrades fast	EPISUITE
Fugacity		
Air %	7.4	EPISUITE
Water %	40.6	EPISUITE
Soil %	51.9	EPISUITE
Sediment %	0.0718	EPISUITE
Bioconcentration factor (BCF)	3 (aquatic organisms)	HSDB, 2011
Biotransformation half-life	0.02866 days	EPISUITE

Name	Magnesium Chloride
Synonyms	Magnesium dichloride
CAS number	7786-30-3
Molecular formula	$MgCl_2$
Product name	M275

Physical Properties	Value	Reference
Phase/state	Thin white to grey granules and / or flakes	HSDB, 2011
Molecular weight	95.21 g/mol (rapid heating)	HSDB, 2011
Melting point	118 ^{o}C (with decomposition)	Merck, 1996
	712 ^{o}C (rapid heating)	HSDB, 2011
Boiling point	1,412^{o}C	HSDB, 2011
Solubility	56.g/100g at 20^{o}C (in water)	HSDB, 2011

Other Relevant Factors	Value	Reference
Reactivity		
Species & Reaction type	Decomposes to magnesium oxichloride and hydrochloric acid. 2MgCl2 + H20 -> Mg20*Cl2 + 2 HCL	IUCLID, 2000
	Magnesium chloride is one of the constituents in a salt mixture that reacts with water giving a moderate heat evolution and an alkaline effect	IUCLID, 2000
pH		
acid / alkaline	NA	
pH (5% solution)	5% in water is neutral to litmus.	JBaker, 2009

The asterisk (*) denotes several meanings depending upon the field you are viewing. An asterisk can be used in these fields:

- *Concentration:* This means the reported concentration has been recalculated to meet database conformity. For example, the concentration unit was reported as Molar units, but the standard database unit is micrograms per liter. Another example would be if the reported value was as a metal compound and it was recalculated to the ion level. Note: These recalculations are no longer performed.
- *Endpoint*: This denotes the reported endpoint acronym provided was modified to conform to the standard database acronym terminology. For example, if the author reported a TLM, the endpoint was coded as an LC50*.

Name	Non crystalline silica
Synonyms	Amorphous silica (silicon dioxide), silica gel, diatomaceous earth, silica anhydrous, colloidal silica.
CAS number	NA (7631-86-9 amorphous silica surrogate used for information on chemical information sheet)
Molecular formula	O_2Si
Product name	

Physical Properties	Value	Reference
Phase/state	Amorphous powder.	HSDB, 2011
Molecular weight	60.1 g/mol	HSDB, 2011
Melting point	1710^{o}C	HSDB, 2011
Boiling point	2230^{o}C	HSDB, 2011
Solubility	Insoluble	HSDB, 2011

Other Relevant Factors	Value	Reference
Reactivity		
Species & Reaction type	Vinyl acetate vapour may react vigorously in contact with silica gel.	HSDB, 2011
pH	NA

Name	Sodium Carbonate
Synonyms	Soda ash, Solvay soda, bisodium carbonate, carbonic acid, crystol carbonate, disodium carbonate, sodium carbonate.
CAS number	497-19-8
Molecular formula	Na_2Co_3
Product name	Soda Ash M3

Physical Properties	Value	Reference
Phase/state	White powder	HSDB, 2011
Molecular weight	105.99 g/mol	HSDB, 2011
Melting point	851°C	HSDB, 2011
Boiling point	Decomposition	IPCS, 2011
Solubility	Soluble in 3.5 parts water 215g/l at 20°C	HSDB, 2011 IPCS, 2011

Other Relevant Factor	Value	Reference
Reactivity		
Species Reaction type	The sodium ion will not adsorb to particulate matter, but remains in the aqueous phase. In water the carbonate ions will re-equilibrate until an equilibrium is established. The main equilibria are: HCO3 - ↔ CO3 2- + H+ pKa = 10.35 CO2 + H2O ↔ HCO3 - + H+ pKa = 6.33 The carbonate will finally be incorporated into the inorganic and organic carbon cycle.	IPCS, 2011
pH		
acid / alkaline	Aqeous solution is strongly alkaline	Merck, 1996
pH (solution)	Strong alkaline compound with a pH of 11.6 for a 0.1M aqeous solution.	IPCS, 2011

The asterisk (*) denotes several meanings depending upon the field you are viewing. An asterisk can be used in these fields:

- *Concentration:* This means the reported concentration has been recalculated to meet database conformity. For example, the concentration unit was reported as Molar units, but the standard database unit is micrograms per liter. Another example would be if the reported value was as a metal compound and it was recalculated to the ion level. Note: These recalculations are no longer performed.
- *Endpoint*: This denotes the reported endpoint acronym provided was modified to conform to the standard database acronym terminology. For example, if the author reported a TLM, the endpoint was coded as an LC50*.

WHO, 2006: Guidelines for Drinking-water Quality 2006.

IARC, 2009: IARC Monographs on the Evaluation of Carcinogenic Risks to Humans. International Agency for Research on Cancer. World Health Organisation. Classification: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to carcinogenicity to humans; Group 4: Probably not carcinogenic to humans.

ECOTOX, United States Environmental Protection Agency ECOTOX database for alkylbenzyldimethyl quaternary ammonium compounds chlorides (only quaternary ammonium compound in the database with toxicity data for several phyla); and [1] data presented as geometric mean (range), N=4.

Name	Tetrasodium ethylenediaminetetraacetate
Synonyms	Tetrasodium ethylenediaminetetraacetate, Tetrasodium EDTA, Acetic Acid, N,N'-1,2-Ethanediyl bis[N-(carboxymethyl)glycine, sodium salt
CAS number	64-02-8
Molecular formula	$C_{10}H_{16}N_2O_8Na_4$
Product name	Not specified

Physical Properties	Value	Reference
Phase/state	White powder	HSDB, 2011
Molecular weight	380.17 g/mol	HSDB, 2011
Melting point	>300 ^{o}C	HSDB, 2011
Boiling point	572.7 ^{o}C (estimate)	EPISUITE
Density/ specific gravity	6.9 lb/gal apparent density	HSDB 2011
Vapour pressure	1.49 x 10 $^{-12}$ mm Hg at 25 ^{o}C	EPISUITE
Solubility	500 g/L at 20 ^{o}C in water	HSDB, 2011
	1 x 10^{6} at 25 ^{o}C in water	EPISUITE
Henrys law constant	1.18x10 $^{-23}$ atm m^3/mol	HSDB, 2011
Organic carbon partition coefficient (Koc)	312.7	EPISUITE
Log organic carbon partition coefficient (log Koc)	2.495	EPISUITE
Log octanol-water partition coefficient (log Kow)	-13.17*	EPISUITE

*This molar concentration is not possible but results from the extreme Log Kow value predicted by EPISUITE. It has not been relied upon. A measured value for Kow for this compound could not be found.

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	NA	
Aerobic BOD	NA	
Anaerobic BOD	NA	
Biowin7 (Anaerobic Model Prediction)	Biodegrades fast	EPISUITE
Fugacity		
Air %	1.36 x 10^{-12}	EPISUITE
Water %	18.9	EPISUITE
Soil %	80.9	EPISUITE
Sediment %	0.198	EPISUITE
Bioconcentration factor (BCF)	3.162	EPISUITE
Biotransformation half-life	7.617x 10^{-6}	EPISUITE

ECOTOX, US Environmental Protection Agency ECOTOX database contained over 500 test results, data selected as LC50 and NOEC from common species used for toxicity testing with non-physiological end points; data presented as [1] geometric mean (range) N=3; [2] geometric mean (range) N=11; [3] geometric mean (range) N=5; [4] geometric mean (range) N=7.
ECOSAR, US Environmental Protection Agency ECOSAR database , Ecological Structure Activity Relationships (ECOSAR) Class Program. Accessed at http://www.epa.gov/oppt/newchems/tools/21ecosar.htm.

Name	Vinylidene Chloride / Methylacrylate
Synonyms	1,1 dichlorothene, 1,1 dichloroethylene, 1,1 DCE, vinylidene dichloride.
CAS number	25038-72-6 (surrogate CAS 75-35-4 (1,1 DCE) used for the information on the chemical information sheet).
Molecular formula	$C_2H_2Cl_2$
Product name	Not specified

Physical Properties	Value	Reference
Phase/state	Colourless liquid	HSDB, 2011
Molecular weight	96.94 g/mol	HSDB, 2011
Melting point	-122.5 ^{o}C	HSDB, 2011
Boiling point	31.7 ^{o}C	HSDB, 2011
Density/ specific gravity	1.2129 at 20^{o}C	HSDB, 2011
Vapour pressure	600 mm Hg at 25^{o}C	HSDB, 2011
Solubility	2,420 mg/L at 25^{o}C	HSDB, 2011
Henrys law constant	2.61 x 10^{-2} atm cu m/mole at 24 ^{o}C	HSDB, 2011
Organic carbon partition coefficient (Koc)	64	HSDB, 2011
Log organic carbon partition coefficient (log Koc)	1.80618	HSDB, 2011
Log octanol-water partition coefficient (log Kow)	2.12	EPISUITE

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	Biodegradation in water is not expected to be an important fate process, with 1,1-DCE reaching 0% of its theoretical BOD in 4 weeks(11).	HSDB, 2011
Aerobic BOD	1,1-DCE had a biodegradation half-life of 1.25 yrs in ground water from a former manufacturing facility.	HSDB, 2011
Anaerobic BOD	In the microcosms designed to simulate a groundwater environment, 50% of the 1,1-dichloroethylene disappeared in 5-6 months	HSDB, 2011
Biowin7 (Anaerobic Model Prediction)	Does not biodegrades fast	EPISUITE
Fugacity		
Air %	20.8	EPISUITE
Water %	75.1	EPISUITE
Soil %	3.8	EPISUITE
Sediment %	0.257	EPISUITE
Bioconcentration factor (BCF)	11.81	EPISUITE
Biotransformation half-life	0.614 days	EPISUITE

Notes: 1 EPI Suite^{TM} v4.0, United States Environmental Protection Agency.

Name	Alkyaryl Sulfonate
Synonyms	Sodium dodecylbenzenesulfonate, benzenesulfonic acid dodecyl sodium salt.
CAS number	25155-30-0
Molecular formula	C18 H30 O3 S.Na
Product name	ClearFRAC LT

Physical Properties	Value	Reference
Phase/state	White to light yellow flakes, granules or powder	HSDB 2012
Molecular weight	348.49	HSDB 2012
Melting point	287.63 ^{o}C	EPISUITE
Boiling point	660.62 ^{o}C	EPISUITE
Density/ specific gravity	1.0 at 20^{o}C for 60% slurry	HSDB 2012
Vapour pressure	2.29 x 10^{-15} mm Hg at 20°C-25^{o}C	EPISUITE
Solubility	8 x 10^{2} mg/L at 25 ^{o}C	HSDB 2012
Henrys law constant	6.27 x 10^{-8} atm m^{3}/mole	HSDB 2012
Log organic carbon partition coefficient (log Koc)	2.04 (calculated from 110.5 Koc)	HSDB, 2012
Organic carbon partition coefficient (Koc)	110.5 (based on solubility of 800 mg/L)	HSDB 2012
Log octanol-water partition coefficient (log Kow)	0.45	HSDB 2012

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation		
Aerobic BOD	appears to be susceptible to aerobic biodegradation with a BOD5/TOC ratio of 0.95	HSDB 2012
Anaerobic BOD	In anaerobic digester sludge assays, strong inhibition was found with 0.69 and 0.1 g/L sodium dodecylbenzenesulfonate	HSDB 2012
Biowin7 (Anaerobic Model Prediction)	Does not biodegrade fast	EPISUITE
Fugacity		
Air %	0.644	EPISUITE
Water %	18.6	EPISUITE
Soil %	74	EPISUITE
Sediment %	6.8	EPISUITE
Bioconcentration factor (BCF)	64 to 130	HSDB 2012
Biotransformation half-life	1.322 days	EPISUITE

Notes: EPI Suite™ v4.0, United States Environmental Protection Agency.

WHO, 2006: Guidelines for Drinking-water Quality 2006.

IARC, 2009: IARC Monographs on the Evaluation of Carcinogenic Risks to Humans. International Agency for Research on Cancer. World Health Organisation. Classification: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to carcinogenicity to humans; Group 4: Probably not carcinogenic to humans.

ECOTOX, US Environmental Protection Agency ECOTOX database contained over 500 test results, data selected as LC50 and NOEC from common species used for toxicity testing with non-physiological end points; data presented as [1] geometric mean (range) N=3; [2] geometric mean (range) N=11; [3] geometric mean (range) N=5; [4] geometric mean (range) N=7.
ECOSAR, US Environmental Protection Agency ECOSAR database , Ecological Structure Activity Relationships (ECOSAR) Class Program. Accessed at http://www.epa.gov/oppt/newchems/tools/21ecosar.htm.

Name	Nitrogen (liquid form)
Synonyms	Nitrogen elemental, liquid nitrogen, diatomic nitrogen, dinitrogen, mol nitrogen.
CAS number	7727-37-9
Molecular formula	N2
Product name	ClearFRAC LT

Physical Properties	Value	Reference
Phase/state	Colourless Gas	HSDB, 2012
Molecular weight	28.013	HSDB, 2012
Melting point	-210.01 ^{o}C	HSDB, 2012
Boiling point	-195.79 ^{o}C	HSDB, 2012
Density/ specific gravity	1.251 g/L at 0^{o}C	HSDB, 2012
Vapour pressure	1 atm @ 77.347 degrees kelvin	HSDB, 2012
Solubility	1.81 x 10^{4} mg/L at 21 ^{o}C	HSDB, 2012
Henrys law constant	1.94 x 10^{-2} atm m^{3}/mole (Bond Method)[1]	EPISUITE
Log organic carbon partition coefficient (log Koc)	1.121 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	0.67	HSDB, 2012

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	NA	
Aerobic BOD	NA	
Anaerobic BOD	NA	
Biowin7 (Anaerobic Model Prediction)	Does not biodegrade fast	EPISUITE
Fugacity		
Air %	55.4	EPISUITE
Water %	42.2	EPISUITE
Soil %	2.21	EPISUITE
Sediment %	0.101	EPISUITE
Bioconcentration factor (BCF)	3.162 L/kg	EPISUITE
Biotransformation half-life	0.03954 days	EPISUITE

Name	Propane 1,2 diol
Synonyms	Methylethylene glycol, propylene glycol, trimethyl glycol
CAS number	57-55-6
Molecular formula	C3-H8-O2
Product name	ClearFRAC LT

Physical Properties	Value	Reference
Phase/state	Colourless viscous liquid	HSDB, 2012
Molecular weight	76.09	HSDB, 2012
Melting point	-60 ^{o}C	HSDB, 2012
Boiling point	187.6 ^{o}C	HSDB, 2012
Density/ specific gravity	1.0361 g/cm^{3} at 20^{o}C	HSDB, 2012
Vapour pressure	0.13 mm Hg at 25^{o}C	HSDB, 2012
Solubility	1 x 10^{6} mg/L at 20 ^{o}C	HSDB ,2012
Henrys law constant	1.3 x 10^{-8} atm m^{3}/mole	HSDB, 2012
Organic carbon partition coefficient (Koc)	1	HSDB, 2012
Log organic carbon partition coefficient (log Koc)	0 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	-0.92	HSDB 2012

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation		
Aerobic BOD	Propylene glycol achieved 64% of its theoretical BOD using a sewage inoculum and a 5 day incubation period	HSDB, 2012
Anaerobic BOD	Using an activated sludge or digester sludge incubated under anaerobic conditions, propylene glycol was completely degraded within 5-9 days	HSDB, 2012
Biowin7 (Anaerobic Model Prediction)	Does biodegrade fast	EPISUITE
Fugacity		
Air %	0.397	EPISUITE
Water %	34.5	EPISUITE
Soil %	65	EPISUITE
Sediment %	0.061	EPISUITE
Bioconcentration factor (BCF)	3	HSDB, 2012
Biotransformation half-life	0.0087 days	EPISUITE

Name	Sodium Hypochlorite
Synonyms	Hypochlorous acid, sodium salt; clorox
CAS number	10377-60-3
Molecular formula	NaOCl
Product name	BE-7

Physical Properties	Value	Reference
Phase/state	liquid	2
Molecular weight	74.4 g/mol	2
Melting point	18^{o}C	2
Boiling point	111^{o}C	2
Solubility	29.3 g/100 g (0 deg C) in water	2

Other Relevant Factors	Value	Reference
Reactivity		
Species	$NaOCl + H_2O \leftrightarrow NaOH + HOCl \leftrightarrow Na^+ + OH^- + H^+ + OCl^-$	
Reaction type	Acid/base, saponification, anti-microbial, oxidising agent	2
pH		
acid / alkaline	alkaline	2
pH (5% solution)	11.1 – 11.6

Name	Trimethyl -3- [(1-oxooctadecyl) amino] propylammonium methyl sulphate Product sheet based on modelled data
Synonyms	1-Propanaminium, N,N,N-trimethyl-3-[(1-oxooctadecyl)amino]- ,methyl sulphate, 2-(3 aminophenyl) n phenylacetamide, N,N,N - Trimethyl -3-((1-oxooctadecyl) amino) -1- propanaminium methyl sulfate
CAS number	19277-88-4
Molecular formula	C25 H54 N2O5S1
Product name	ClearFRAC LT

Physical Properties	Value	Reference
Phase/state	NA	
Molecular weight	494.78	EPISUITE
Melting point	331.56^{o}C	EPISUITE
Boiling point	754.66 ^{o}C	EPISUITE
Density/ specific gravity	NA	
Vapour pressure	1.89 x 10^{-18} mm Hg at 25^{o}C	EPISUITE
Solubility	0.01494 mg/L at 25 ^{o}C	EPISUITE
Henrys law constant	2.3 x 10^{-20} atm m^{3}/mole (Bond Method)	EPISUITE
Log organic carbon partition coefficient (log Koc)	5.285 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	5.52 (KOWWIN)	EPISUITE

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	NA	
Aerobic BOD	NA	
Anaerobic BOD	NA	
Biowin7 (Anaerobic Model Prediction)	Does not biodegrade fast	EPISUITE
Fugacity		
Air %	4.66 x 10^{-5}	EPISUITE
Water %	4.56	EPISUITE
Soil %	55.2	EPISUITE
Sediment %	40.2	EPISUITE
Bioconcentration factor (BCF)	70.79 L/kg wet wt	EPISUITE
Biotransformation half-life	1.034 days	EPISUITE

Name	Bentonite
Synonyms	Colloidal clay, montmorillonite, otaylite, trixoton
CAS number	121888-68-4 (1302-78-9 given by HSDB, 2011)*
Molecular formula	$C_6H_{12}N_4O_9$
Product name	

*All EPISUITE data were collected for the chemical 1302-78-9

Physical Properties	Value	Reference
Phase/state	The colour in the massive condition varies from yellowish-white to almost black. The powder is cream to pale brown.	HSDB, 2011
Molecular weight	284.18 g/mol	EPISUITE
Melting point	101.93 (estimate)	EPISUITE
	NA	IUCLID, 2000
Boiling point	344.50 (estimate)	EPISUITE
	NA	IUCLID, 2000
Solubility	Insoluble	HSDB, 2011

Other Relevant Factors	Value	Reference
Reactivity		
Species	NA	
Reaction type	NA	
pH		
acid / alkaline	pH 7-9 at 10 g/L and 20^{oC}	IUCLID, 2000
pH (10% solution)	In prescence of water it forms translucent suspension with a pH of around 9.	HSDB, 2011

Notes: 1 EPI Suite^{TM} v4.0, United States Environmental Protection Agency.

Name	Calcium chloride
Synonyms	Calcium II chloride, Calcium dichloride
CAS number	10043-52-4
Molecular formula	$CaCl_2$
Product name	

Physical Properties	Value	Reference
Phase/state	Colourless, cubic crystals	HSDB, 2011
Molecular weight	110.99 g/mol	HSDB, 2011
Melting point	772^{o}C	HSDB, 2011
Boiling point	1670 ^{o}C	HSDB, 2011
Solubility	745 g/L at 20^{o}C	INCHEM2002
	Freely soluble in water	HSDB, 2011
	9.797 x 10^4 mg/L at 25^{o}C	EPISUITE

Other Relevant Factors	Value	Reference
Reactivity		
Species & Reaction type	Reacts violently with heat generation in water. Forms flammable gases and evolves hydrogen when reacted with zinc. When heated to decomposition emits toxic fumes of hydrogen chloride.	HSDB, 2011
pH		
acid / alkaline	Salt	HSDB, 2011

Notes: 1 EPI Suite™ v4.0, United States Environmental Protection Agency.

Name	Coco dimethylaminopropyl betaine
Synonyms	COCAMIDOPROPYL BETAINE
CAS number	61789-40-0
Molecular formula	C19H39N2O3
Product name	HC-2A

Physical Properties	Value	Reference
Phase/state	Liquid	IUCLID 2000
Molecular weight	343.53 g/mol	EPISUITE
Melting point	<0 ^{o}C	IUCLID 2000
Boiling point	100 ^{o}C	IUCLID 2000
Density/ specific gravity	1.04 g/cm^{3} at 20^{o}C	IUCLID 2000
Vapour pressure	Not applicable	IUCLID 2000
Solubility	1755 g/m^{3} at 25^{o}C	EPISUITE
Henrys law constant	6.19x10^{-21} atm m^{3}/mole	EPISUITE
Log organic carbon partition coefficient (log Koc)	2.811 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	Not applicable. Substance dissociates in aqueous solution	IUCLID 2000
	0.69 (KOWWIN)	EPISUITE

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	At 20 mg/L, 100% degraded after 20 days. Readily biodegradable	IUCLID 2000
Aerobic BOD	NA	
Anaerobic BOD	NA	
Biowin 7 (Anaerobic Model Prediction)	Does not biodegrade fast	EPISUITE

Aquatic Toxicological Data

Estimated acute toxicity data							
Species name	**Common name**	**Endpoint**	**Effect**	**Effect measure**	**Test time (days)**	**Conc (µg/L)**	**Reference**
*Lowest acute LC/EC50 values for fish, daphnia and algae		LC/EC50				1300-2000	SIDS 2006
Estimated chronic toxicity data							
*Oncorhynchus mykiss	Fish	NOEC			Chronic test	160	SIDS 2006
*Daphnia magna	Daphnid	NOEC			Chronic test	30	SIDS 2006
*Desmodesmus subspicatus	Green Algae	NOEC			Chronic test	90	SIDS 2006
	*Daphnids	NOEC				932	SIDS 2006
	*Algae	NOEC			3	9860	SIDS 2006
	*Algae	NOEC				3550	SIDS 2006

Aquatic toxicological data is based on cocamidopropyl betaine data cited with the SIDS (2006) alkylamidopropyl betaines document.

* SIDS profile provided does not cite the studies where aquatic ecotoxicological data was sourced. Unable to find full SIDS document at http://www.chem.unep.ch/irptc/sids/OECDSIDS/index1.htm

MOR/ MORT : Mortality

POP: Population

GPOP: Population changes, general

Effect values within the same species (e.g Desmodesmus subspicatus, Daphnia magna) have shown high variability. Recent studies in accordance with OECD TG 211 and 201 have resulted in a lower aquatic toxicity for cocamidapropyl betaine (SIDS, 2006).

Name	Ethanol
Synonyms	Ethyl Alcohol, ethyl hydrate, ethyl hydroxide.
CAS number	64-17-5
Molecular formula	C_2H_6O
Product name	GasPerm 1100

Physical Properties	Value	Reference
Phase/state	Clear, colourless, very mobile liquid	HSDB, 2011
Molecular weight	46.07 g/mol	HSDB, 2011
Melting point	-114.1 ^{o}C	HSDB, 2011
Boiling point	78.5 ^{o}C	HSDB, 2011
Density/ specific gravity	0.789 at 20^{o}C	HSDB, 2011
Vapour pressure	59.3 mm Hg at 25^{o}C	HSDB, 2011
Solubility	Miscible in water	HSDB, 2011
	7.921 x 10^5 mg/L at 25^{o}C	EPISUITE
Henrys law constant	5 x 10^{-6} atm m^3/mole	HSDB, 2011
Organic carbon partition coefficient (Koc)	1	HSDB, 2011
Log organic carbon partition coefficient (log Koc)	0.019 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	-0.31	HSDB, 2011

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	Biodegradation is expected to occur rapidly in the environment, unlikely to be persistent in the environment. Not expected to adsorb to suspended solids and sediment.	HSDB, 2011
Aerobic BOD	74% BOD in 5 days	HSDB, 2011
Anaerobic BOD	1.5 days under denitrifying conditions, 5 days under iron - reducing conditions.	HSDB, 2011
Biowin7 (Anaerobic Model Prediction)	Biodegrades fast	EPISUITE
Fugacity		
Air %	7.4	EPISUITE
Water %	40.6	EPISUITE
Soil %	51.9	EPISUITE
Sediment %	0.0718	EPISUITE
Bioconcentration factor (BCF)	3 (aquatic organisms)	HSDB, 2011
Biotransformation half-life	0.02866 days	EPISUITE

WHO, 2006: Guidelines for Drinking-water Quality 2006.

IARC, 2009: IARC Monographs on the Evaluation of Carcinogenic Risks to Humans. International Agency for Research on Cancer. World Health Organisation. Classification: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to carcinogenicity to humans; Group 4: Probably not carcinogenic to humans.

ECOTOX, US Environmental Protection Agency ECOTOX database contained over 500 test results, data selected as LC50 and NOEC from common species used for toxicity testing with non-physiological end points; data presented as [1] geometric mean (range) N=3; [2] geometric mean (range) N=11; [3] geometric mean (range) N=5; [4] geometric mean (range) N=7.
ECOSAR, US Environmental Protection Agency ECOSAR database , Ecological Structure Activity Relationships (ECOSAR) Class Program. Accessed at http://www.epa.gov/oppt/newchems/tools/21ecosar.htm.

Name	Sodium Chloride
Synonyms	Salt
CAS number	7647-14-5
Molecular formula	NaCl
Product name	HpH Breaker

Physical Properties	Value	Reference
Phase/state	Colourless transparent crystals or white crystalline powder.	HSDB, 2011
Molecular weight	58.44 g/mol	HSDB, 2011
Melting point	801 ^{o}C	HSDB, 2011
Boiling point	1 mm Hg at 865^{o}C	HSDB, 2011
Solubility	3.57 x 10 ^{5} g/m^{3} at 25^{o}C	HSDB, 2011
	35.7 g/100 ml of water at 0^{o}C	HSDB, 2011
	One gram dissolves in 2.8ml of water at 25^{o}C	Merck, 1996

Other Relevant Factors	Value	Reference
Reactivity	zero	MSDS, 2010
Species	NA	
Reaction type	NA	
pH		
acid / alkaline	In aqueous solution is neutral	HSDB, 2011
pH (10% solution)	6.7 to 7.3	HSDB, 2011

Notes: 1. Haliburton Material Safety Data Sheet HPH Breaker. Issue Date:4 January 2010.

Note that two LC50 values for fathead minnows were removed as they appeared to be outliers in the large LC50 dataset and could not be verified. The LC50 values were 5440 and 6280 µg/L. The reference is Brenda Mines Sulphate and Molybdenum Toxicity Testing Proj.Rep.No.2-11-825/826, Prepared for Noranda Mining and Exploration Inc., Brenda Mines Div., B.C.(): -

WHO, 2006: Guidelines for Drinking-water Quality 2006.

IARC, 2009: IARC Monographs on the Evaluation of Carcinogenic Risks to Humans. International Agency for Research on Cancer. World Health Organisation. Classification: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to carcinogenicity to humans; Group 4: Probably not carcinogenic to humans.

ECOTOX, US Environmental Protection Agency ECOTOX database contained over 500 test results, data selected as LC50 and NOEC from common species used for toxicity testing with non-physiological end points; data presented as [1] geometric mean (range) N=3; [2] geometric mean (range) N=11; [3] geometric mean (range) N=5; [4] geometric mean (range) N=7.

Name	Sodium Hydroxide
Synonyms	Sodium hydroxide
CAS number	1310-73-2
Molecular formula	NaOH
Product name	BE-7

Physical Properties	Value	Reference
Phase/state	White orthogonal crystals	HSDB, 2011
Molecular weight	40 g/mol	HSDB, 2011
Melting point	323^{o}C	HSDB, 2011
Boiling point	1388^{o}C	HSDB, 2011
Solubility	1 g dissolves in 0.9 ml water	HSDB, 2011

Other Relevant Factors	Value	Reference
Reactivity		
Species	OH^-/NaOH	
Reaction type	Acid/base	
pH		
acid / alkaline	Alkaline	HSDB, 2011
pH (5% solution)	11	HSDB, 2011

Notes: 1. Halliburton Material Safety Data Sheet M275. Issue Date:16 July 2003.
2. Hazardous Substances Data Bank (HSDB) National library of Medicine accessed on line 24 March 2011.

ADWG, 2004: Australian drinking water guidelines . Endorsed by NHMRC 10 – 11 April 2003. National Health and Medical Research Council, Natural Resource Management Ministerial Council.

NZDWS, 2008: Drinking-water standards for New Zealand 2005 (Revised 2008). Ministry of Health, Wellington.

WHO, 2006: Guidelines for Drinking-water Quality 2006.

IARC, 2009: IARC Monographs on the Evaluation of Carcinogenic Risks to Humans. International Agency for Research on Cancer. World Health Organisation. Classification: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to carcinogenicity to humans; Group 4: Probably not carcinogenic to humans.

ECOTOX, US Environmental Protection Agency ECOTOX database contained over 500 test results, data selected as LC50 and NOEC from common species used for toxicity testing with non-physiological end points; data presented as [1] geometric mean (range) N=3; [2] geometric mean (range) N=11; [3] geometric mean (range) N=5; [4] geometric mean (range) N=7.
Hickey CW; N.Z. J Mar Freshwater Res 23 (1): 131-137 (1989). Available from the ECOTOX database on Boric acid (10043-35-3) at: http://www.epa.gov/cgi-bin/ecotox_quick_search as of May 13, 2005.
European Chemicals Bureau; IUCLID Dataset, Boric acid (10043-35-3) (2000 CD-ROM edition). Available from, as of May 18, 2005: http://ecb.jrc.it/esis/esis.php.

Name	Sodium sulfate
Synonyms	Bisodium sulphate, disodium monosulfate, disodium sulphate,
CAS number	7757-82-6
Molecular formula	$H_2O_4S_2Na$
Product name	

Physical Properties	Value	Reference
Phase/state	White powder or orthorhombic bipyramid crystals	HSDB, 2011
Molecular weight	142.06 g/mol	HSDB, 2011
Melting point	888 ^oC	HSDB, 2011
Boiling point	>890 ^oC	IUCLID, 2000
Solubility	Soluble in 3.6 parts water at 33^oC	HSDB, 2011

Other Relevant Factors	Value	Reference
Reactivity		
Species	NA	
Reaction type	NA	
pH		
acid / alkaline	Sodium salt of sulphuric acid	IUCLID, 2000

Notes: 1 EPI Suite™ v4.0, United States Environmental Protection Agency.

2. Hazardous Substances Data Bank (HSDB) National library of Medicine (sodium sulfate) accessed on line : 7 June 2011.

3. IUCLID, 2000. European Commission: European Chemicals Bureau. Accessed on 7 June 2011. Accessed at : http://ecb.jrc.ec.europa.eu/iuclid-datasheet/7757826.pdf

The asterisk (*) denotes several meanings depending upon the field you are viewing. An asterisk can be used in these fields:

- *Concentration:* This means the reported concentration has been recalculated to meet database conformity. For example, the concentration unit was reported as Molar units, but the standard database unit is micrograms per liter. Another example would be if the reported value was as a metal compound and it was recalculated to the ion level. Note: These recalculations are no longer performed.
- *Endpoint*: This denotes the reported endpoint acronym provided was modified to conform to the standard database acronym terminology. For example, if the author reported a TLM, the endpoint was coded as an LC50*.

Name	Sodium sulfite
Synonyms	Sulfurous acid, disodium salt, disodium sulfite
CAS number	7757-83-7
Molecular formula	$H_2O_3S.{}_2Na$
Product name	

Physical Properties	Value	Reference
Phase/state	Small crystals or powder	HSDB, 2011
Molecular weight	126.044 g/mol	HSDB, 2011
Melting point	340.4 (estimate)	EPISUITE
Boiling point	773.7 (estimate)	EPISUITE
Solubility	Soluble in 3.2 parts water	HSDB, 2011

Other Relevant Factors	Value	Reference
Reactivity		
Species	No oxidizing properties	
Reaction type	Sodium sulphite reacts with acids to liberate sulphur dioxide. It sometimes reacts with oxidizing agents violently.	IUCLID 2000
pH		
acid / alkaline	Salt	HSDB, 2011

Notes: 1 EPI Suite™ v4.0, United States Environmental Protection Agency.

Classification: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to carcinogenicity to humans; Group 4: Probably not carcinogenic to humans.

ECOTOX, US Environmental Protection Agency ECOTOX database contained over 500 test results, data selected as LC50 and NOEC from common species used for toxicity testing with non-physiological end points; data presented as [1] geometric mean (range) N=3; [2] geometric mean (range) N=11; [3] geometric mean (range) N=5; [4] geometric mean (range) N=7.

ECOSAR, US Environmental Protection Agency ECOSAR database , Ecological Structure Activity Relationships (ECOSAR) Class Program. Accessed at http://www.epa.gov/oppt/newchems/tools/21ecosar.htm.

Name	Sweet Orange Oil
Synonyms	Orange oil (composition of orange oil differs from sweet orange oil; its aldehyde content is lower and its ester content higher).
CAS number	68647-72-3 or 8008-57-9
Molecular formula	C10H16
Product name	GasPerm 1100

Physical Properties	Value	Reference
Phase/state	Yellow to reddish yellow liquid.	HSDB, 2011
Molecular weight	136.24	EPISUITE
Melting point	-40.76	EPISUITE
Boiling point	176 ^{o}C	Chembook 2011
Density/ specific gravity	0.844 - 0.847 at 20 ^{o}C	HSDB, 2011
Vapour pressure	NA	HSDB, 2011
Solubility	Slightly soluble in water	HSDB, 2011
	4.581 mg/L at 25 ^{o}C	EPISUITE
Henrys law constant	3.8 x 10 $^{-1}$ atm-m^{3} / mol (Bond Method)	EPISUITE
Log organic carbon partition coefficient (log Koc)	3.049 (MCI Method)	EPISUITE
Log octanol-water partition coefficient (log Kow)	4.83	EPISUITE

Persistence/ Bioaccumulation	Value	Reference
Aquatic biodegradation	NA	HSDB, 2011
Aerobic BOD	NA	HSDB, 2011
Anaerobic BOD	NA	HSDB, 2011
Biowin7 (Anaerobic Model Prediction)	Does not biograde fast	EPISUITE
Fugacity		
Air %	0.298	EPISUITE
Water %	50.2	EPISUITE
Soil %	47.5	EPISUITE
Sediment %	1.96	EPISUITE
Bioconcentration factor (BCF)	360.5	EPISUITE
Biotransformation half-life	3.531 days	EPISUITE

APPENDIX F HUMAN HEALTH TOXICOLOGICAL PROFILES

APPENDIX F.1 SCHLUMBERGER GUAR BASED SYSTEMS

Toxicity Profile

Acetic acid
(CAS No. 64-19-7)

Acetic acid dissociates in aqueous media to H^+ and the acetate anion ($CH_3CO_2^-$). It is naturally occurring as the acid in apple cider vinegar and other fruit-derived products. It and several of its salts are commonly used as food additives (*e.g.*, as flavor enhancers) and are listed as Generally Recognized as Safe (GRAS) by the U.S. Food and Drug Administration (FDA).

pH: 2.5 at 50 g/L and 20°C
pK_a: 4.76 @ 20°C

Acute Toxicity

The oral LD_{50} in rats is 4,950 mg/kg, and the dermal LD_{50} in rabbits is 1,060 mg/kg. The 4-hour LC_{50} in rats is 11.4 mg/L.

Irritation

In the EU, acetic acid is classified as a skin and eye irritant at concentrations <25%. At ≥25%, it is classified as corrosive to the skin.

Sensitization

No data are available.

Repeated Dose Toxicity

In an 8-month study, rats dosed with 60 mg/kg acetic acid (three times per week) developed hyperplasia in the esophagus and forestomach.

Genotoxicity

Acetic acid was not mutagenic to *Salmonella typhimurium* strains TA 98, TA 100, TA 1535, TA 1537, and TA 1538 in an *in vitro* bacterial mutation assay with or without metabolic activation. Acetic acid (in media adjusted to a pH of 8.5) was also not genotoxic in an *in vitro* chromosomal aberration test using Chinese Hamster Ovary cells with or without metabolic activation.

Carcinogenicity

No adequate carcinogenicity studies have been conducted on acetic acid.

Reproductive Toxicity

No studies could be located.

Developmental Toxicity

There were no effects on implantations or on maternal or fetal survival in mice, rats, or rabbits at doses up to 1,600 mg/kg.

Key Study/Critical Effect for Screening Criteria

There are no repeat dose toxicity studies that were considered adequate for human health risk assessment. The only study reported on the toxicity of acetic acid by oral gavage showed effects of irritation (probably due to the pH of acetic acid) at the site of contact in the gastrointestinal tract. No systemic effects were reported.

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) has maintained a group ADI of "not limited" for acetic acid and its potassium and sodium salts.

The Australian drinking water guidance value for pH may apply to acetic acid.

Toxicity Profile

Ammonium C6-C10 Alcohol Ethoxysulfate
(CAS No. 68187-17-7)

Alcohol ethoxysulfates (AES) are a widely used class of anionic surfactants. No data could be located on alcohol ethoxysulfates in the C6 to C10 range. Thus, the C12-C14 alcohol ethoxysulfates were used to read-across to the C6-C10 alcohol ethoxysulfates.

In the HERA report, the alcohol ethoxysulfate family covers commercial grades of linear-type primary alcohol ethoxysulfates of either sodium, ammonium or triethanolamine (TEA) salts. Sodium salts of AES are by far the commonly used grades.

Acute Toxicity

Alcohol ethoxysulfates are considered to have a low order of acute oral toxicity in the rat. In two guideline compliant acute oral toxicity studies, the oral LD_{50}s were >2,000 mg/kg.

Irritation

The irritation potential of AES is concentration dependent. Materials with concentrations >70% are moderately to severely irritating to rabbit skin . At concentrations between 10 and 30%, the AES solutions exhibit mild to moderate irritancy under the conditions of an occluded patch test. AES concentrations below 1% are virtually non-irritating under the conditions of the acute skin irritation testing protocol.

The triisopranolammonium salt of C12-14E2S (90% active material) and NaC12-14E2S (28% active material) were shown to be moderately to severely irritating to rabbit eyes.
It has been shown that solutions containing less than 1- 10% AES are slightly to moderately irritating to eyes and below 1%, AES solutions are virtually non-irritating.

Sensitization

AES are not considered to be skin sensitizers.

Repeated Dose Toxicity

Rats were given by oral gavage 0, 25, 75 or 225 mg/kg NaC12-14AE2S for 90 days. Four animals died during the treatment period and were considered incidental, and three animals died due to experimental procedures. There were no treatment-related effects on total body weight gain, food and water consumption, and systemic effects. In the 225

mg/kg animals, hyperplasia, submucosal edema and chronic ulceration were seen in the forestomach. In groups 25 and 75 mg/kg groups, 3/10 animals showed small eosinophilic foci in the stratified epithelium of the forestomach. The LOAEL appears to be 25 mg/kg/day and the NOAEL was not determined.

Rats were fed in their diet 0, 40, 200, 500, 1,000 or 5,000 ppm NaC12-15E3S for 90 days. All animals survived until the end of the study. There were no treatment-related effects on clinical signs and body weights in females. Male body weights were significantly higher than controls in the 500 ppm group from week 10 onwards and at 200 ppm at weeks 11 and 13. At higher concentrations, there was no difference in body weights from the control values. At 5,000 ppm, male and female liver weights were significantly increased, and absolute testes weights were also increased; however, there was no significant difference with control animals when adjusted for terminal body weight. These organ weight changes were not accompanied by any histopathological, clinical chemical or hematological changes and were therefore considered to be adaptive in nature and not a toxic effect of the test substance. The NOAEL for this study is 5,000 ppm (250 mg/kg/day).

Rats were given in their diet 0, 0.1 or 0.5% C12 AE3S for 2 years. There were no treatment-related effects (including tumor incidence). The results of this study suggests that the NOAEL was 0.5% (250 mg/kg/day).

Rats were given in their drinking water 0 or 0.1% C12AE3S for two years. There were no treatment-related effects on survival, growth, food consumption, body weights, clinical laboratory findings, hematology and urinalyses. The only unusual finding was slight, but consistently higher water consumption by all rats receiving the test compound in their drinking water and a significant difference in the empty cecum to body weight ratio of females. Absolute organ weights were all comparable to controls and no consistent gross or histopathology was found. The incidence and types of tumors observed in the treated group was similar to that of control animals. The NOAEL for this study is 0.1% (75 mg/kg/day).

Genotoxicity

AES are not genotoxic when tested either *in vitro* or *in vivo*.

Carcinogenicity

The available oral and dermal long term toxicity/carcinogenicity studies, even if not performed according to accepted guidelines for carcinogenicity bioassays, appear to be conducted and documented in an acceptable manner. There is sufficient evidence that AES was carcinogenic in these studies.

Reproductive Toxicity

AES did not adversely affect reproduction in the rat and the NOAEL for reproductive effects was > 300 mg/kg. Slight systemic effects were observed in the parental and F_1 generation with a NOAEL of 86 and 149 mg/kg, respectively.

Developmental Toxicity

Based on the available information, there is sufficient evidence to conclude that AES are not teratogenic or a developmental toxicants. A NOAEL of >1,000 mg/kg/day can be estimated for teratogenicity and embryotoxicity, and the NOAEL for developmental toxicity appears to be >750 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

A LOAEL of 225 mg/kg/day was reported in the 90-day oral gavage study on NaC12-14AE2S based on forestomach lesions in the rat. These lesions appear to be a localized effect due to the irritation properties of the test substance. No systemic toxicity was observed in this study. In contrast, when the test AES were given in the diet or in drinking water, not such irritation effects of the gastrointestinal tract was noted. This study will not be considered for the derivation of a drinking water guidance value since repeated dosing by oral gavage (a single daily oral bolus) is not a realistic human exposure scenario. Furthermore, 90-day and 2-year dietary and drinking water studies exist. The lowest NOAEL from the 90-day and 2-year dietary and drinking water studies is 75 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 75/100 = 0.75 mg/kg/day

Drinking water guidance value = 2.6 ppm

Toxicity Profile

Amorphous/Non-crystalline Silica
(CAS No. 7631-86-9[1])

Silica Gel
(CAS No. 112926-00-8)

Amorphous silica and silica gel have been reviewed in the OECD-SIDS program (OECD, 2004a,b).

The CAS No. 7631-86-9 is the general CAS No. for silicon dioxide which includes all forms of silicas (*e.g.* also crystalline and natural forms). Only the silica sub-classes, the synthetic amorphous silicas, are the subject of this assessment.

Synthetic amorphous silicas (SAS) are in powder form which have a low water solubility: ≤70 mg/L

Toxicokinetics

After oral ingestion, there is no accumulation of SAS in body tissues. Upon cessation of exposure, rapid elimination occurs. Intestinal resorption appears to be insignificant in animals and humans. In a human study, the small apparent increases in the urine output of human volunteers were remarkably low as compared with the high dose of 2,500 mg SiO_2 applied.

After daily oral administration of 1,500 mg/kg SAS (FK 700) as aqueous suspension to rats for one month, there was no accumulation of SiO_2 in the body: the average SiO_2 content was: 1.5 µg in the liver, 6.4 µg in the kidney, and 5.3 µg in the spleen. The corresponding control values were 1.8, 7.2 and 7.8 µg SiO_2, respectively.

In a similar experiment in rats receiving 20 daily oral doses of 100 mg SAS (HDK V15) per animal (about 500 mg/kg) each, tissue values were slightly increased in liver and kidney: in liver 4.2 µg (control value 1.8 µg), in the spleen 5.5 µg (7.2 µg) and in the kidneys 14.2 µg (7.8 µg).

In 12 human volunteers, no significant increased renal excretion of SiO_2 was found following single oral ingestion of 2,500 mg (AEROSIL 175 and FK 700).

Acute Toxicity

The acute oral administration of various forms of SAS (aqueous suspension or gel) failed to produce signs of toxicity or deaths in treated animals with LD_{50} values greater than the

top doses applied, either by gavage: >3100 to >20000 mg/kg in mice and rats; or in the diet for 24 hours.

Irritation

Synthetic amorphous silicas are not irritating to the skin of rabbits exposed to 0.19 g (one case) or 0.5 g of dry or moistened test item under occlusive conditions for 4 or 24 hours. All products tested as a powder (0.1 g) have shown no or only weak and transient irritating effects on the conjunctivae of the eyes of rabbits with the iris and cornea not affected at all.

Sensitization

No experimental data are available on the synthetic amorphous silicas. Medical surveillance records on workers gave no evidence of skin sensitization over decades of practical experience.

Repeated Dose Toxicity/Carcinogenicity

Fischer rats and B6C3F_1 mice were administered SAS in the diet at levels of 0, 1.25, 2.5, and 5% for 102 weeks. The animals were in good condition throughout and showed high survival. The tumor responses in all organs of SAS-fed rats and mice were not statistically significantly different from the controls. The NOAEL for rats and mice were 2,500 and 6,500 mg/kg/day, respectively.

Genotoxicity

There is no evidence for synthetic amorphous silica to induce mutations either *in vitro* or *in vivo* using standard genotoxicity tests.

Reproductive Toxicity

An early limited one-generation study on rats gave no evidence of adverse effects on reproduction performan*ce* at 500 mg/kg/day, the highest dose tested (NOAEL). But the reliability is poor due to the small group size of animals.

Developmental Toxicity

SAS was examined for embryotoxic and developmental effects during the gestation phase in various animals species, rat, mouse, rabbit and hamster, at oral doses up to 1,600 mg/kg/day. . There were no significant signs of maternal or embryotoxic/developmental toxic effects in any species tested. The number of abnormalities seen in either soft or skeletal tissues of the test groups did not differ from the frequencies occurring spontaneously in the control animals.

Key Study/Critical Effect for Screening Criteria

The lowest NOAEL from the two-year dietary study was 2,500 mg/kg/day for rats.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 2,500/100 = 2.5 mg/kg/day

Drinking water guidance value = 0.09 ppm

Toxicity Profile

Reaction mass of 5-chloro-2-methyl-4-isothiazolin-3-one and 2-methyl-2H-isothiazolin-3-one [3:1]
(CAS No. 55965-84-9)

Acute Toxicity

The oral LD_{50} of Kathon WT (1.5% a.i.) is >5,000 mg/kg (>75 mg a.i./kg) in male rats and >3,310 mg/kg (~49.6 mg a.i./kg) in female rats. The oral LD_{50} of Acticide 14 (14% a.i.) is 472-490 mg/kg (~66 to 69 mg a.i./kg) in rats (combined sexes); and 465 mg/kg (69 mg a.i./kg) in male rats and 393 mg/kg (59 mg a.i./kg) in female rats.

The dermal LD_{50} of Kathon CG is >5,000 mg/kg (>75 mg a.i./kg) in female rabbits. The dermal LD_{50} of Acticide 14 (14% a.i.) is 1,008 mg/kg (141 mg a.i./kg) in rats (combined sexes).

The inhalation LC_{50} of Kathon 886F (13.9% a.i.) in male and female rats is 2.36 mg/L (0.33 mg a.i./L).

Irritation

Undiluted Kathon MW (1.5% a.i.) and Acticide 14 (14% a.i.) were corrosive to rabbit skin. Undiluted Kathon CG was severely irritating to the eyes of rabbits. Kathon RH 886T at 100 ppm (0.01% a.i.) was non-irritating to the eyes of rabbits.

Sensitization

CMI/MI has been tested in the guinea pig Buehler and Magnusson-Kligman tests and has been shown to be a strong skin sensitizer. It is also a strong contact allergen in humans.

Repeat Dose Toxicity

Rats were exposed to CMI/MI in a powdered commercial diet. CMI/MI concentrations were increased over the 13-week period (initial concentration up to week 2, intermediate concentration week 3-4, final concentration week 5 to 13). Concentrations in the control and CMI/MI groups were: 0/0/0, 40/57/80, 132/187/260, 400/570/800 ppm. There were no mortalities and no effects on body weight or food consumption. In each group, some animals showed slight alopecia or reddened raw or scabbed areas on the skin. There were no other differences in general behavior or appearance. There were no treatment-related changes in hematological, biochemical, urinary parameters nor any pathology. No systemic toxicity was observed up to and including the highest dose of either CMI/MI

(800 ppm, equivalent 29.1 mg a.i./kg/day). The NOAEL in this study is 800 ppm (29.1 mg a.i. /kg/day).

Rats were exposed to CMI/MI via their drinking water at concentrations of 25, 75 or 225 ppm a.i. for three months (equivalent to an average intake of 2.38, 6.28 and 16.3 mg/kg/day in males and 4.06, 10.8, and 24.7 mg/kg/day in females). Two additional groups of rats were given tap water or tap water containing the inorganic ions present in the CMI/MI solution, at a concentration equal to that in the high dose group (225 ppm). This solution is referred to as the ion control solution. There were no mortalities in either sex at any dose level. There were no treatment-related effects on body weight up to the mid dose. A significant decrease in body weight was seen in males at the high dose during the first two weeks of the study. Food consumption was significantly decreased in males at all dose levels and in females mid and high dose groups during the first few weeks of dosing. Water consumption was significantly decreased at all concentrations. No overt clinical signs or ophthalmic were seen in any group throughout the 13 week toxicity or the reproductive phase. No adverse effects were seen in the examinations. No hematological treatment-related changes were seen in either sex at any dose level. There was a significant decrease in globulin and an increase in the albumin/globulin (A/G) ratio in males in both the high concentration and in the ion control groups, after 13 weeks of treatment. A significant decrease in total protein was also seen high concentration group, but was not seen in the ion control group. Females in the high concentration group showed a modest (40%) increase in SGOT (AST, aspartate aminotransferase) levels after 13 weeks of dosing. No changes were observed at any dose in mixed-function oxidase activities of the liver. At the end of 13 weeks of treatment, there was a significant increase in relative liver weight in males and in relative kidney weight in females at the high concentration but without any correlative changes in organ pathology. Histology revealed a local irritation of the glandular mucosa of the stomach in 7 of 15 males and 5 of 15 females at the high concentration. These subtle low level changes did not occur at the low or mid concentration nor were they present in either control group. No other compound related changes were seen. Reproductive organs at all doses were comparable to the control. The NOEL in this study was considered to be 75 ppm a.i. (equivalent to 6.28 and 10.8 mg/kg body weight/day in males and females, respectively), based primarily on irritation of the glandular stomach at the high dose. The No Observed Adverse Effect Level (NOAEL) is 225 ppm a.i. (equivalent to 16.3 and 24.7 mg/kg body weight/day in males and females, respectively), the highest dose tested, since no adverse effects were observed on the histopathology of any tissues or organs distant from the site of dosing.

Genotoxicity

The results of the *in vitro* mutagenicity tests were equivocal. In bacterial reverse mutation tests, CMI/MI was positive in *Salmonella* strain TA100 but was predominantly negative in other strains commonly tested strains. CMI/MI was mutagenic in the mouse lymphoma assay with and without metabolic activation. Effects at the Tk locus was seen both with and without S-9, but were enhanced with S9 mix. CMI/MI was not genotoxic

in the *in vitro* unscheduled DNA synthesis (UDS) assay with primary rat hepatocytes or in an *in vitro* chromosomal aberration test with Chinese hamster lung cells.

The *in vivo* studies indicated that CMI/MI does not have relevant mutagenic potential *in vivo*. The positive mutagenic effect of CMI/MI found in *in vitro* gene mutation assays was not confirmed in the sex-linked recessive lethal test in *Drosophila melanogaster* nor in two unscheduled DNA synthesis (UDS) studies in the rat. CMI/MI also did not show any increase in cells with micronuclei in mice nor did it induce chromosomal aberrations in rat bone marrow cells.

Carcinogenicity

In a two-year rat chronic study, Kathon 886 is given as 14.2% active ingredient with a pH between 2-3. In the document with compiled batch information for Kathon the active ingredient is 13.2, [10.13 % CMI/ 3.85% MI] with 15.4% magnesium nitrate and 9.0% magnesium chloride. The dose levels were 0, 30, 100 and 300 ppm (equivalent to: 0, 2.0, 6.6, 17.2 mg a.i./kg/day in males and 0, 3.1, 9.8, 25.7 mg a.i./kg/day in females. There were no deaths. There were no treatment-related effects on body weight or body weight gain at doses or food consumption up to and including the mid dose group. A treatment-related and concentration-dependent decrease in water consumption was seen in both sexes in all treated groups throughout the study. These decreases ranged from 0-22% at low dose 3-30% at mid dose and 15-40% at high dose. These decreases appear to be due to the unpalatability of the CMI/MI and not its inorganic stabilizer salts since the water consumption in the salt control was comparable to the tap water control throughout the study. Based on the average daily water consumption, the high dose was judged to be a maximum tolerated dose. The decreases in body weight and body weight gain were seen in high dose animals throughout the study and may be secondary to decreased water consumption. No treatment-related clinical effects were recorded. No treatment-related ophthalmic, hematological. biochemical or urinary changes were noted. Organ weights were comparable to the control. No effects on type or incidence of neoplasms were seen at up to and including the high dose (males: 17.2 a.i.; females 25.7 mg a.i./kg/day). Slight to moderate forestomach hyperplasia was seen at both mid and high dose groups. Gastric irritation was the primary effect observed. No adverse effects on the histopathology of any other tissues/organs were observed away from the site of dosing. No systemic effects were observed. The NOEL in this study was considered to be 30 ppm a.i. (2.0 to 3.1 mg a.i./kg/day), based primarily on gastric irritation of the stomach at 100 and 300 ppm a.i.. The NOAEL was considered to be 300 ppm a.i. (17.2 to 25.7 mg/a.i./kg/day), since no evidence of systemic toxicity was observed at any dose and there was no adverse effects on the histopathology of any tissues/organs distant from the site of dosing at any dose.

Reproductive/Developmental Toxicity

A one-generation reproductive toxicity study was combined with the 13-week drinking

water study reported above in the repeated dose toxicity section. Reproductive capability was similar in all groups. Litter size and survival at birth was also similar in all groups. One dam at the high concentration lost the entire litter by day 4 due to a lactation problem. This is not uncommon and was not considered treatment related. Pups of the other high concentration group dams, except one, survived and thrived to day 21. Thus, no adverse effects were observed on reproductive capability of male and female rats and no effects were observed on fetal health or pup survival (to day 21) up to and including the high dose (equivalent to 16.3 and 24.7 mg/kg/day in males and females, respectively].

In a two-generation reproductive toxicity study, rats were dosed with CMI/MI (Kathon 886F: 11.1% CMI, 3.7% MI a.i.) at concentrations of 0 (control), 0 (magnesium salt control), 30, 100 or 300 ppm a.i. For the P1 generation, this was equivalent to 0, 2.8-4.4; 8.5-11.8, and 22.7-28.0 mg a.i./kg/day; and in the P2 generation 0, 4.3-5.5, 13.4-16.0, and 35.7-39.1 mg a.i./kg/day. There were no treatment related effects on survival, food consumption or overt signs of toxicity. A decrease in bodyweight gain was noted initially in the P1 generation. This was thought to be linked to reduced water consumption since significant dose-related reduction in water consumption was seen at all concentrations in both the P1 and P2 generations, during the premating, gestation and lactation stages. Treatment-related histopathological changes were seen in the stomach in the P1 and P2 generation. These included erosions of the glandular mucosa, edema and inflammation in the submucosa of the glandular and nonglandular stomach, with hyperplasia and hyperkeratosis of the nonglandular stomach at the 100 and 300 ppm a.i. Other histopathological changes were seen but were not dose dependent.The estrus cycle in P1 or P2 females at any treatment level was comparable with the controls, as was the sperm motility, morphology, testicular sperm count or caudal epididymal reserves of P1 or P2 males. All other endpoints (gestation index, gestation length, number of pups per litter or treatment-related gross findings in F1 or F2 pups) were similar to those in the controls in either generation. The study authors considered that rats exposed to CMI/MI in the drinking water through two generations had a NOAEL of 30 ppm a.i. (2.8-4.4 mg/kg/day in the P1 animals; 4.3-5.5 mg/kg/day in the P2 animals) for parental animal toxicity, based on the gastric irritation of stomach at higher doses. The NOEL for reproductive toxicity is 300 ppm a.i. (22.7-28.0 mg/kg/day in the P1 animals; 35.7-39.1 mg/kg/day in the P2 animals), the highest dose tested. There were no effects on fertility or fetal development at any dose level.

In a rat oral gavage developmental toxicity study on Kathon 886 (13.9% a.i.), the developmental NOEL for CMI/MI is >15 mg a.i./kg during organogenesis (highest dose tested). In a rat oral gavage developmental toxicity study on Acticide 14 (10.2% CMi/ 4% MI), the NOAEL for maternal toxicity is <3.95 mg a.i./kg; the NOAEL for teratogenicity is >19.6 mg a.i./kg; and the NOAEL for embryotoxicity is >19.6 mg a.i./kg. In a rabbit oral gavage developmental toxicity study on Acticide 14 (10.2% CMI/ 4% MI), the developmental NOAEL is >5.49 mg a.i./kg; the NOAELs for maternal toxicity and fetal toxicity are 1.41 mg a.i./kg. In a rabbit oral gavage developmental toxicity study on Kathon MW (13.9% a.i.), the NOEL for maternal toxicity is 2 mg a.i./kg; the developmental NOEL is 8 mg a.i./kg, the highest dose based on severe

maternal toxicity at 20 mg a.i./kg.

Key Study/Critical Effect for Screening Criteria

A two-year dietary study was conducted in rats with CMI/MI (13.2% active ingredient). No systemic effects were observed. There was, however, gastric irritation of the stomach at 100 and 300 ppm. The NOEL for this study is 30 ppm (equivalent to 2.0 and 3.1 mg a.i./kg/day for males and females, respectively). The NOEL of 2.0 mg/kg/day will be used for deriving a drinking water guidance value.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral Reference Dose = 2/100 = 0.02 mg/kg/day

Drinking water guidance value = 0.07 ppm

EU SCCS (2009). Opinion on the mixture of 5-chloro-2-methyl-4-isothiazolin-3-one and 2-methyl-2H-isothiazol-3-one [3:1], Colipa N^{o} P56, Scientific Committee on Consumer Safety, SCCS/1238/09.

Toxicity Profile

C6-C10 Alcohol Ethoxylates

Alcohol ethoxylates are a class of non-ionic surfactants. The AEs have the basic structure $C_{x-y}AE_n$. The subscript (x-y) following the 'C' indicates the range of carbon chain units. AEs with carbon unit range between C8 to C18 are most commonly used in household detergent products. The hydrocarbon chain can be either linear or branched. AEs also contain an ethylene oxide (E) chain attached to the alcohol. The degree of ethylene oxide polymerization is indicated by the subscript (n) which indicates the average number of ethylene oxide units. In household products the average ethylene oxide chain length commonly ranges between 3 and 12 units.

The toxicity profile of C6-C10 alcohol ethoxylates has been evaluated as part of the class of alcohol ethoxylates ranging from C8 to C15 in the HERA report.

Acute Toxicity

The acute oral LD_{50} of C9-11AE2.5 in rats was calculated to be >4,000 mg/kg and <10,000 mg/kg. The acute oral LD_{50} of C7-9AE6 in rats was determined to be <2,000 mg/kg. The acute oral LD_{50} of C9-11AE8 in fasted rats was found to be 1,200 mg/kg. The oral LD_{50} in rats for C12-13AE6.5 is 2,100 mg/kg. The oral LD_{50} in rats for C12-15AE7 is 1,700 mg/kg. For C14-15AE11, the acute oral LD_{50} values were reported to be 720 mg/kg (neat) and 1,800 mg/kg (given as 50% (m/v) solution in corn oil). The oral LD_{50} in rats for C12-15AE11 is >2,00 mg/kg for males and between 1,000 and 2,000 mg/kg for females. The oral LD_{50} in rats for C14-15AE13 is 1,100 and 1,000 mg/kg in two separate studies.

The dermal LD_{50} of C7-9AE6 was >2 g/kg. The dermal LD_{50} values for AEs with an alkyl chain length of 9 – 11 carbon atoms in three different rat studies were determined to be >2,000 mg/kg and >4,000 mg/kg. An acute dermal LD_{50} value of >2,000 mg/kg was determined for C12-14AE3 and C12-14AE6 in two separate studies. The acute dermal LD_{50} of C12-15AE7 was determined to be >2,000 mg/kg.

The acute rat 4h-LC_{50} of C9-11AE5 generated as a mist was determined to be >0.22 mg/L. Talmage (1994) reported that alcohol ethoxylates were not acutely toxic to rats at concentrations less than or equal to their saturated vapor concentrations in air. Acute toxic thresholds were reached only when animals were exposed to the undiluted test chemical in the form of a respirable mist or aerosol. Under these conditions, 1- or 4-hour inhalation LC_{50} values ranged from 1.5 to 20.7 mg/L. Some studies reported no mortalities (1-hours LC_{50} -study) occurred at concentrations as high as 52 mg/L.

Irritation

Alcohol ethoxylates with varying alkyl chain lengths and ethoxylation degree were found to be slightly to severely irritating to skin in rabbits and rats. The degree of irritation was dependant on the type of patches used (open application versus full occlusion), the exposure time as well as the concentration of the test material. In humans, AEs are less irritating to skin than in animals. Neat applications of a range AEs in a 4h human patch test did not warrant these chemicals to be classified as skin irritants under EU legislation, while the same AEs would have been classified for skin irritation on the basis of animal data.

Alcohol ethoxylates range from mildly to severely irritating to rabbit eyes. Rinsing the eyes directly after exposure with water for 20 to 30 seconds greatly reduced the severity of the effects such that these products produced only mildly irritating effects. The degree of irritation is concentration-dependent as dilutions in water cause proportionally lower irritation. Generally, concentration of 0.1% were non-irritating, and concentrations of 1 to 10% ranged from slight to moderately irritating. No relationship could be established between the chemical structures of the tested AEs and their eye irritation responses.

Sensitization

Alcohol ethoxylates should not be considered as skin sensitizers. A substantial amount of skin sensitization studies in guinea pigs following either the Magnusson-Kligman maximization or the Buehler testing protocol are available to evaluate the skin sensitization potential of AEs. Although a mild skin sensitization reaction was observed in a study following the Magnusson-Kligman protocol, the weight of evidence clearly supports the assessment that AEs should not be considered as skin sensitizers. This is further supported by clinical and market data that demonstrate the absence skin sensitization responses to AEs when tested under the conditions of the HRIPT or when used in AE containing consumer products.

Repeated Dose Toxicity

C10AE5 was fed to rats at doses of 0, 125, 250 or 500 mg/kg for 90 days. There were not treatment-related clinical signs, body weight gain, food consumption or feed efficiency. There was a slight increase in absolute liver weights as well as a trend toward a dose-dependent increase in the liver weight/body weight ratio, with a statistically significant increase in the high dose group. However, the histological evaluation did not reveal any indication of hepatotoxicity and therefore the increase in liver weights was not interpreted to be a toxicological effect. It can be considered to be an adaptive response as a result of extensive metabolism of the test compound by the liver. There were no other gross or histopathological changes that were considered treatment-related. The NOAEL for this study can be considered to be 500 mg/kg/day.

Rats were given in their diet 0, 125, 250, 500, 1,000 and 3,000 ppm C9-11AE6 for 90

days. There were no signs of toxicity at any dose level. The NOAEL is 3,000 ppm (approximately 150 mg/kg/day).

Rats were given in their diet 0. 04, 0.2 and 1.0% C9-11AE8 for 90 days. Lower body weight gain and decreased food consumption were noted in the 1% males and females and in the 0.2% females from week 1 through the end of the study. Further statistical analyses revealed a significant decrease in the mean body weight gain noted in the 1% females and the decreases in mean food consumption noted in the 1% males and females. The differences noted in the 0.2% females were not statistically significant. The investigators considered these observations to be the result of poor palatability of the test substance. There were no other treatment-related effects. The NOAEL for this study is 1.0% (about 400 mg/kg/day).

Rats were fed C12-15AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% and 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the 0.25% and higher dose groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the 0.25% groups and higher. There were not treatment-related changes in hematology, urinary and clinical chemistry parameters. The histological examination of the liver at necropsy revealed hepatocytic enlargement at 0.125% and higher, suggesting an increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (102 mg/kg/day).

Rats were fed C12-14AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% and 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the 0.25% and higher dose groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the 0.25% groups and higher. There were not treatment-related changes in hematology, urinary and clinical chemistry parameters. The histological examination of the liver at necropsy revealed hepatocyte cell enlargement at 0.125% and higher, suggesting an increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (110 mg/kg/day).

Wistar rats were fed C14-15AE7 in the diet at concentrations of 0, 300, 1,000, 3,000, and 10,000 ppm for 90 days. All animals survived until their scheduled necropsy date. Significant treatment-related effects on body weight (*i.e.*, reduced mean body weights in males at 10,000 ppm and in females at 3,000 ppm), food intake (*i.e.*, reduced intake in both sexes at 10,000 ppm and at 3,000 ppm for females), organ weights (*i.e.*, increased relative liver weight in both sexes at 3,000 and 10,000 ppm and in females also at 1,000 ppm; increased spleen weight in males at 10,000 ppm; clinical chemistry (*i.e.*, confined to 10,000 ppm dose groups; significantly higher urea, chloride and potassium levels in males; significantly higher urea, chloride and cholesterol levels in females) and hematology (*i.e.*, in both sexes at 10,000 ppm and in males also at 3,000 ppm increased total leukocytes and lymphocytes; females at 10,000 ppm showed depression in numbers

of neutrophils, mean cell volume and mean cell hemoglobin) were identified in one or both sexes fed with dietary concentrations of 3,000 and 10,000 ppm. There were no compound-related histopathological effects at any dose level. Minor, but statistically significant changes in liver weight, kidney weights and plasma urea concentration were recorded in female rats in the 1,000 ppm group were not of toxicological significance. The NOAEL for this study is 1,000 ppm (50 mg/kg/day).

Rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1%, 0.5% and 1% for 90 days. There were no treatment-related changes in body weight, food intake, and organ weights including those of the reproductive system, clinical chemistry and hematology at any treatment level. The NOAEL is 1% in the diet, which corresponded to 700 and 785 mg/kg/day for males and females, respectively.

Rats were fed C12-13AE6.5 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Rats were fed C14-15AE7 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Charles River rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1, 0.5 and 1% for two years. There was a dose-related decrease in body weights in the 0.5 and 1% females and in the 1% males, the likely cause being poor palatability of the diet. At study termination, elevated organ-to-body weight ratios were noted for the liver, kidney, heart and thyroid/parathyroid glands in the 1% dietary group. The only significant histopathological finding prevalent in all dose groups was a dose-related increase in incidence of focal myocarditis at 12 months but not at study termination at 2 years. No other treatment-related histopathology was noted. The NOAEL was established at the 0.5% dietary level, which corresponds to about 162 and 190 mg/kg/day for males and females, respectively.

Genotoxicity

In all available *in vitro* and *in vivo* genotoxicity assays, there was no indication of genetic toxicity of broad range of structurally different alcohol ethoxylates.

Carcinogenicity

It can be concluded that alcohol ethoxylates as a class are not carcinogenic by the oral route based of available oral long term toxicity/carcinogenicity studies on AEs.

Charles River rats were given in their diet 0, 0.1, 0.5 or 1% C14-15AE7 for two years. There was no treatment-related changes in general behavior and appearance. The survival rate of the test animals was comparable if not better than the controls. Body weights of 0.5% females and 1% males and females had significantly lower weight gains than the control. There were no treatment-related effects on organ weights and tumor incidence.

Sprague-Dawley rats were fed C14-15AE7 at 0.1, 0.5 and 1% in the diet for two years. A treatment-related body weight depression was observed in females at the two highest treatment levels and in males at the 1% dose level, probably due to the poor palatability of the diet. There was no evidence for any carcinogenic activity.

Sprague-Dawley rats were fed C12-13AE6.5 in the diet at doses up to 1% (500 mg/kg/day). Reduced food consumption was noted at the higher dose levels (*i.e.*, 0.5 and 1% for females and 1% for males), resulting in a lower body weight gain compared to the control group. No treatment-related histopathology was found and no increase in tumor incidence was observed.

Reproductive Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg/day). No treatment related effects in the parents or pups on general behavior, appearance or survival were observed. Fertility of treated groups was comparable with the controls. The only observation was related to a reduced weight gain of parental rats and pups relative to the control at the 0.5% dose level. The NOAEL for reproduction was therefore set at the highest dose level which was 0.5% dietary level (250 mg/kg/day).

In a two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg). The control group and the six treated groups comprised of 25 male and 25 female animals. Three of the groups received the compound continuously during the study. In the other three groups the females received the compound only during gestational days 6-15 and the males were untreated. No treatment-related changes in behavior or appearance were observed in the parental rats or pups throughout the study. Female rats from the 0.5% continuous treatment group gained slightly less body weight compared to control females. No other consistent differences in body weight were observed. Food consumption was similar for control and treated rats. No compound related differences were seen between control and treated rats with respect to fertility, gestation or viability indices. The average 21-day body weights for pups at the 0.5% continuous treatment group were significantly lower as compared to the average pup body weights in the

controls. No other compound-related changes in body weight were observed. None of the deaths of parental rats during the study was considered to be compound-related. Examination of organ weight values revealed that compound-related effects were limited to increased group mean relative liver weights of male and female F_1 from the 0.5% continuous feeding group at the 91-day sacrifice, and increases in group mean relative liver weights of males from the 0.5% continuous feeding group of the F_2 generation at the 60-day and caesarean section sacrifices. No compound-related histopathological lesions were observed in any of the tissues examined from rats for the F_0 and F_1 generations. The NOAEL for reproductive toxicity is at least 0.5% in the diet (250 mg/kg/day).

Developmental Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg/day). General behavior, appearance and survival were not affected by treatment. At the 0.5% dose level, adults and pups gained less weight than the control rats. In the 0.5% dose group, there was a statistical increase in embryo lethality and soft tissue anomalies and at the 0.1% there was a statistical decrease in mean fetal liver weight. Neither of these effects was considered to be treatment-related by the authors as they showed no dose response characteristics. The NOAEL for maternal toxicity is 50 mg/kg/day. The NOAEL for developmental and teratogenicity is 0.1% (50 mg/kg/day).

Pregnant rabbits were given by oral gavage 0, 50, 100 or 200 mg/kg C12AE6 from GD 2 to16. Nine control rabbits and 31 treated rabbits died during the study. Surviving rabbits at the 200 mg/kg dose level generally showed slight losses of body weight. At 100 and 200 mg/kg, ataxia and a slight decrease in body weight was observed in the pregnant animals. In seven treated and two control rabbits early deliveries were recorded. There were no treatment-related effects on corpora lutea, implantations, number of live fetuses and spontaneous abortions. The NOAEL for maternal toxicity is 50 mg/kg/day; the NOAEL for developmental toxicity is 200 mg/kg/day.

In two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg). On the 13th day of the gestation period a representative number of female rats from each treatment group of the FC generation (*i.e.*, pups from the 3rd mating of the F_0 and F_1 parental generation) were sacrificed. Laparotomies were performed and the uterus was examined for uterine abnormalities, normal implantation and resorption sites. Remaining females were sacrificed on gestational day 21. Various maternal and fetal parameters showed occasional values that were significantly different from the corresponding controls. However these were not considered related to the material tested as none occurred at the high feeding level and no dose response for these parameters was apparent. With respect to body weight gains, parental female rats and pups of the high dose group did not gain as much body weight as the control rats. Examination of organ weight values reveal compound related effects were limited to increased group mean liver weighs of male and female P_1 generation from the 0.5% continuous feeding group at the

91 day sacrifice and increase in group mean relative liver weights of males of the 0.5% continuous feeding group of the P_2 generation at the 60 day section sacrifices. The NOAEL for maternal and developmental toxicity was established at the 0.1% in the diet (50 mg/kg/day).

Key Study/Critical Effect for Screening Criteria

AEs of different structures with regard to the length of the alkyl chain and the degree of ethoxylation have been evaluated in a number of 90-day and two-year oral toxicity studies. The lowest NOAEL of AEs for systemic toxicity was established at 50 mg/kg/day in two chronic (two-year) dietary studies on C12-13AE6.5 and C14-15AE7. Effects observed at the LOAEL were related to significantly elevated organ-to-body weight ratios for liver, kidney and heart, although there were no adverse histopathological changes.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 50/100 = 0.5 mg/kg/day

Drinking water guidance value = 1.75 ppm

Toxicity Profile

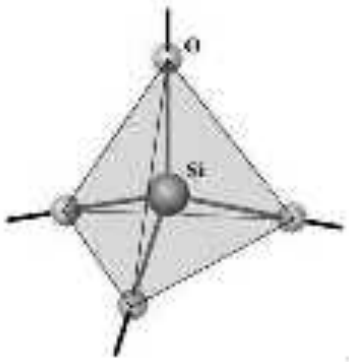
Crystalline Silica, Cristobalite
(CAS No 14464-46-1)

Crystalline Silica, Quartz
(CAS No. 14808-60-7)

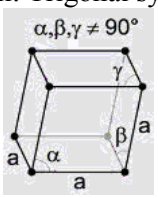
Silica is an off-white granule that occurs naturally in various crystalline and amorphous or other non-crystalline forms. Crystalline silica is characterized by silicon dioxide (SiO_2) molecules oriented in fixed, periodic patterns to form stable crystals. The primary crystalline form of silica is quartz. Other crystalline forms of silica include cristobalite, tripoli and tridymite. Particle size is a key determinate of silica toxicity, since toxicity is restricted to particles that are small enough to be deposited into the target regions of the respiratory tract.

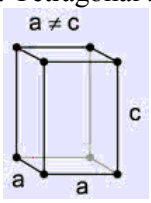
Oral Exposure

No oral studies were located; however, crystalline silica is not expected to exhibit toxicity by the oral route. Although absorption studies were not found for crystalline silica, kinetic studies on amorphous silica show no absorption from the gastrointestinal tract.



Dermal Exposure





No dermal studies were located; however, crystalline silica is not expected to exhibit toxicity by the dermal route.

Inhalation Exposure

See attached OECD-SIDS Initial Targeted Assessment Profile on Quartz and Cristobalite, SIAM 32, 19-21 April 2011.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

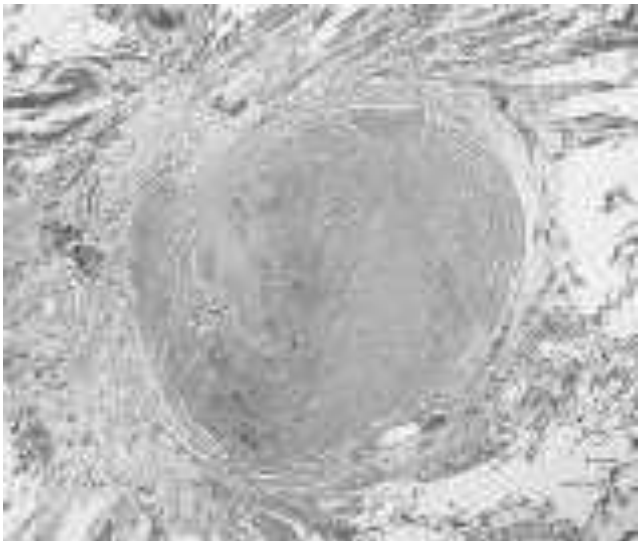


Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3
Sister chromatid exchange	0/1		0/1[c]	1/1	0/2	1/1
Micronucleus	2/3	0/1	2/2[b]	1/1	4/5	1/2
Chromosome aberration	0/1			1/1	0/1	1/1

Oxidative DNA damage		4/5	2/2		2/2	4/5
DNA binding		1/1				1/1
p53 activation		0/1				0/1

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

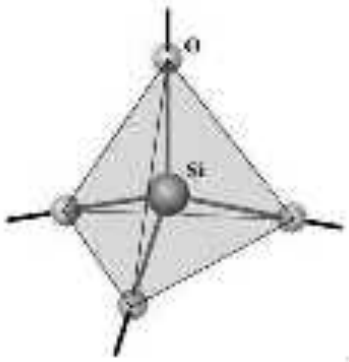
bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

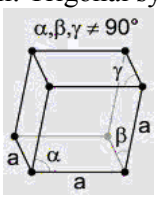
Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

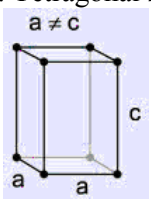
Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.



OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.





RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

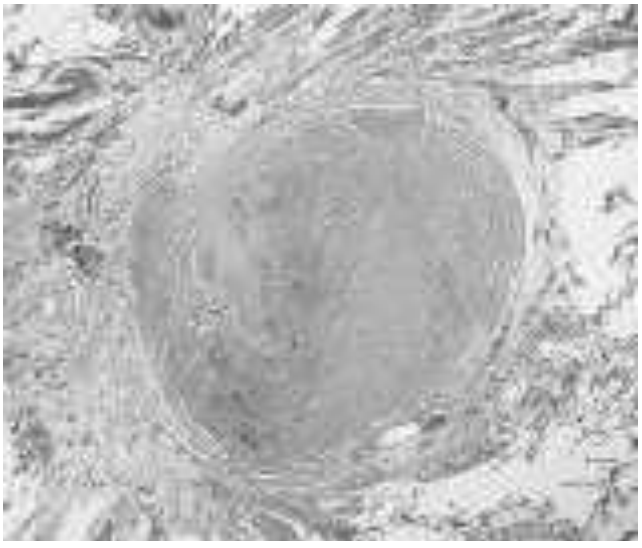

Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

p53 activation		0/1				0/1

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.

OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.

RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

Toxicity Profile

Diammonium peroxidisulfate
Ammonium persulfate
(CAS No. 7727-54-0)

Diammonium peroxisulfate or ammonium persulfate has been reviewed in the OECD-SIDS program (OECD, 2005a,b).

Ammonium persulfate is distributed into the water compartment in the ionic form of the ammonium cation and persulfate ion. The persulfate anion will readily hydrolyze (decompose) into sulfate ions.

Acute Toxicity

The acute oral LD_{50} in rats is 495 mg/kg, and the acute dermal LD_{50}s in rats and rabbits are >5,000 mg/kg. In acute inhalation studies in rats, the 4-hour LC_{50} was generally greater than the maximum attainable concentration (>2,950 mg/m^3 for ammonium persulfate).

Irritation

Ammonium persulfate is slightly irritating to the eye and skin of rabbits. Studies in humans indicate that aqueous solutions of 5% persulfate or higher can cause skin irritation.

Sensitization

Results of animal skin sensitization tests (Buehler Test and Maximization Test) were negative when persulfate was applied topically, but was positive when persulfate was injected intradermally in induction and challenge phases in a non-standard Maximization Test. Numerous dermal challenge tests indicate that all persulfates are dermal and respiratory sensitizers in humans occupationally exposed to persulfates in hairdressing salons and, in one case, in a production facility. In controlled clinical trials with non-occupationally exposed-subjects (ammonium and sodium salts), no sensitization reactions were observed.

Repeated Dose Toxicity

Rats were fed in their diet 0, 300, 1,000 or 3,000 ppm sodium persulfate (0, 23, 100 and 225 mg/kg/day) for 90 days. On day 48 of the study, the concentration of the group

receiving 1,000 ppm was increased to 5,000 ppm for the remainder of the study. Body weights was decreased in the two highest dose groups during the last six weeks of treatment. There were no treatment-related effects on urinalysis, clinical chemistry or hematology parameters. Pathological findings were limited to the 3,000 ppm group only and consisted of necrosis and atrophy of the gastrointestinal tract epithelial lining. The absence of the gastrointestional lesions in the group receiving 1,000 ppm for 8 weeks, followed by 5000 ppm for 5 weeks, indicates that the lesions are related both to concentration in diet (dose) and length of exposure. There were no treatment-related pathological findings in reproductive organs or any other organ system or tissue.

Genotoxicity

Sodium persulfate was not genotoxic in a bacterial reverse mutation (Ames) assay or in an unscheduled DNA synthesis (UDS) assay with rat hepatocytes. It was also not active in a rat bone marrow micronucleus assay and when tested in vivo in a rat hepatocyte UDS assay.

Carcinogenicity

A 51-week dermal study in female SENCAR mice exposed to 0.2 ml of a 200 mg/ml solution of ammonium persulfate showed that ammonium persulfate is neither a tumor promoter nor a complete carcinogen when applied to the skin.

Reproductive/Developmental Toxicity

In a developmental/reproduction study with ammonium persulfate in rats (OECD 421), no effects on reproductive performance, fertility, fetal anomalies, fetal viability, spermatogenesis, spermatogenic cycle were reported up to 250 mg/kg/day. Dose levels were chosen based on the acute lethality studies for the ammonium salt and on a 90-day repeat-dose study in rats with the sodium salt (high dose: 225 mg/kg/day). In the developmental/reproduction study, animals were dosed prior to and during mating through gestation until lactation day 4. There was a transient depression in pup body weight at the 250 mg/kg dose level on lactation day 0 which resolved by day 4. This effect was not considered adverse. Based on the available data, the persulfates do not show evidence of reproductive or developmental toxicity. The NOAEL is 250 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for sulfate may apply to sulfate (500 ppm, health; 250 ppm, aesthetic). There are no existing drinking water guideline values for ammonium ions.

Toxicity Profile

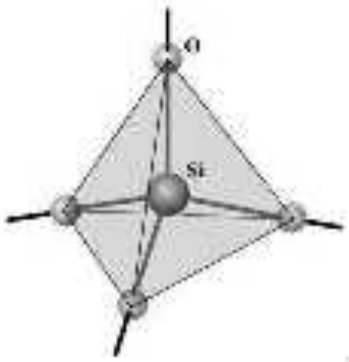
Diatomaceous Earth, Calcined
(CAS No. 91053-39-3)

Silica is an off-white granule that occurs naturally in various crystalline and amorphous or other non-crystalline forms. Crystalline silica is characterized by silicon dioxide (SiO_2) molecules oriented in fixed, periodic patterns to form stable crystals. The primary crystalline form of silica is quartz. Other crystalline forms of silica include cristobalite, tripoli and tridymite. Particle size is a key determinate of silica toxicity, since toxicity is restricted to particles that are small enough to be deposited into the target regions of the respiratory tract.

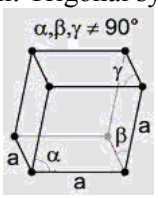
Uncalcined diatomaceous earth (CAS No. 61790-53-2) typically contains around 1% crystalline silica. When diatomaceous earth is subjected to pressure or is processed ("calcined") at temperatures above 1000°C some of the amorphous silica is converted to crystalline silica in the form of cristobalite. Calcined diatomaceous earth can contain anywhere from 1% to 75% cristobalite.

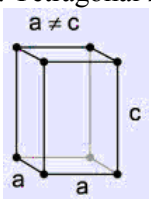
Oral Exposure

No oral studies were located; however, crystalline silica is not expected to exhibit toxicity by the oral route. Although absorption studies were not found for crystalline silica, kinetic studies on amorphous silica show no absorption from the gastrointestinal tract.



Dermal Exposure





No dermal studies were located; however, crystalline silica is not expected to exhibit toxicity by the dermal route.

Inhalation Exposure

See attached OECD-SIDS Initial Targeted Assessment Profile on Quartz and Cristobalite, SIAM 32, 19-21 April 2011.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

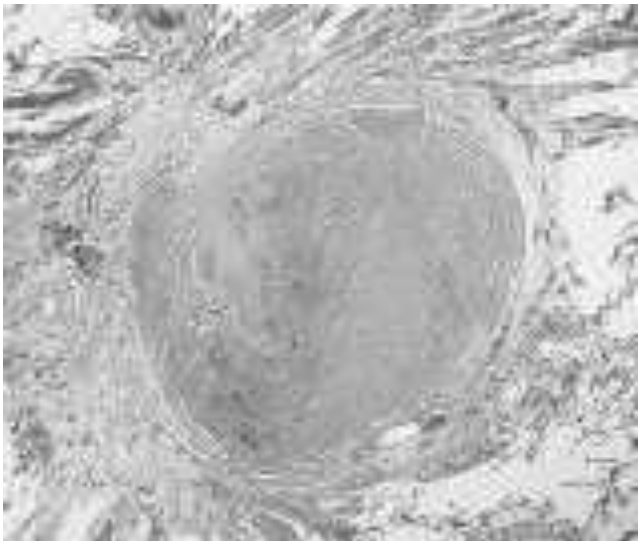


Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3
Sister chromatid exchange	0/1		0/1[c]	1/1	0/2	1/1
Micronucleus	2/3	0/1	2/2[b]	1/1	4/5	1/2
Chromosome aberration	0/1			1/1	0/1	1/1

Cell transformation	4/4				4/4	
Hprt mutation	1/2	2/2[a]	1/1[b]		2/3	2/2
Oxidative DNA damage		4/5	2/2		2/2	4/5
DNA binding		1/1				1/1
p53 activation		0/1				0/1

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

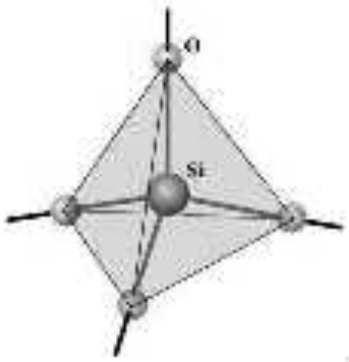
bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

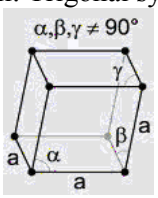
Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

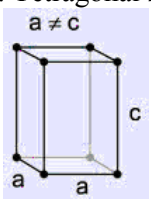
Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.



OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.





RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

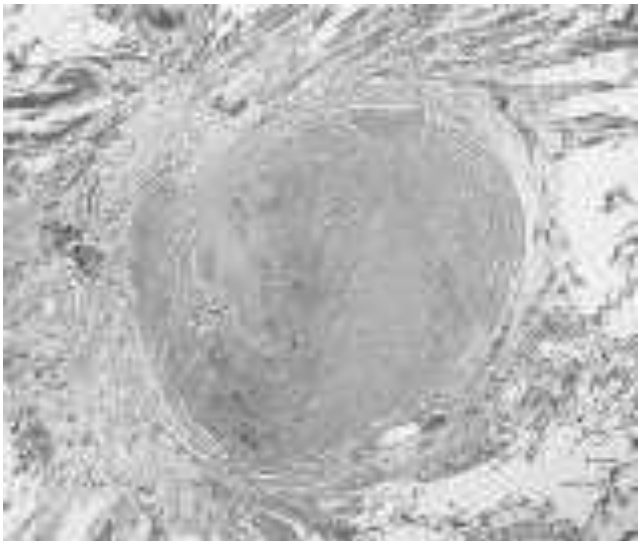

Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3
Sister chromatid exchange	0/1		0/1[c]	1/1	0/2	1/1
Micronucleus	2/3	0/1	2/2[b]	1/1	4/5	1/2

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.

OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.

RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

Toxicity Profile

2-Butoxyethanol
(CAS No. 111-76-2)

2-Butoxyethanol has been reviewed by U.S. EPA (2010) and an oral RfD and inhalation RfC is available in IRIS. An EU Risk Assessment Report is also available on 2-butoxyethanol (2006), an the information in this toxicity profile has been obtained from this report.

Toxicokinetics/Metabolism

Uptake of EGBE by the oral route is rapid and is assumed to be complete (100% absorption). In toxicokinetic studies involving radiolabeled EGBE, the forestomach, liver and kidneys were the organs where most of the radiolabel was found. The major metabolite of EGBE is butoxy acetic acid (BAA). EGBE is metabolized to butoxy aldehyde (BAL) by alcohol dehydrogenases, which is then further metabolized to BAA by aldehyde dehydrogenases. The metabolism of EGBE to BAA appears to be a saturable process. The other metabolites of EGBE are (in order of magnitude): the glucuronide conjugate of EGBE (a competing pathway to BAA formation and whose percentage increases relative to dose), the sulfate-conjugate of EGBE and ethylene glycol. Elimination is rapid and occurs mainly by urinary excretion. EGBE does not accumulate in tissues, and the metabolic profile does not change after repeated exposures compared to acute exposures.

The *in vitro* dermal uptake studies, measuring the rate of absorption of liquid EGBE through human skin, gave results that varied by a factor of 25 (0.064 mg/cm^2/hr for the lowest and 1.66 mg/cm^2/hr for the highest). *In vitro*, rate of absorption is highly dependent on the concentration of the aqueous solution of EGBE used. *In vivo*, in one study, an estimation of the skin penetration gave results in the following range: 7 to 96 nmol/min/cm^2 (0.008 mg/cm^2/hr to 0.0114 mg/cm^2/hr) for pure liquid EGBE. Another study performed with liquid EGBE has showed that greater absorption was found with EGBE 50% in water than neat EGBE (dermal flux 1.34 mg/cm^2/hr and 0.26 mg/cm^2/hr, respectively). This is consistent with data available *in vitro* and in animals. In the EU RAR, where required, a permeation rate of 0.63 mg/cm^2/hr will be used. This is the upper figure from the *in vivo* data and is consistent with the *in vitro* data.

PBPK models has been developed for EGBE and can be used to derive animal to human toxicokinetic extrapolation factors for the inhalation route. These factors are based on the toxokinetics of BAA since this is the metabolite that causes the critical toxic effects.

Acute Toxicity

The oral LD_{50} values are >1,000 mg/kg, and the dermal LD_{50} for rabbits (the most sensitive species) is approximately 500 mg/kg. The 4-hour LC_{50} in rats is approximately 450 ppm (2,214 mg/m^3), with higher values seen in other species.

Suicide cases suggest that the LOEL in humans is about 400 mg/kg. It should be noted that this is a worst case estimation of the LOEL derived from McKinney *et al.* (2000) in which the possible range of exposure was between 400 and 1200 mg/kg.

EGBE causes hematotoxicity *in vivo* in rats, and that the metabolite BAA is considered responsible for this effect. The rat, mouse, hamster and baboon are very sensitive to the hemolytic effects of EGBE; whereas the dog, guinea pig, pig, cat, rabbit and humans (30-times less sensitive than rats) are resistant to EGBE-induced hematoxicity. The hemolysis from EGBE exposure is due to a decrease of erythrocyte deformability due to erythrocyte swelling (this also explains the formation of thrombosis). Newly formed erythrocytes are more resistant than old ones.

Irritation

EGBE is moderately irritating to the skin of rabbits when applied under occlusive conditions for 4 hours. It is also an irritant or severely irritant to the eyes of rabbits.

Sensitization

EGBE is not a skin sensitizer to guinea pigs. A 10 % (v/v) aqueous solution of EGBE was not sensitizing in a human repeat patch test.

Repeated Dose Toxicity (Oral Studies Only)

Male and female Sherman rats were fed in their diets 0, 0.03, 0.125, 0.5 or 2% EGBE for 90 days. The average daily intakes were 0, 18, 76, 310 or 1,540 mg/kg-day. There were no treatment-related deaths and appetite was not affected. Tests for blood in pooled urine sample after 3 and 6 days of testing from the 0, 0.5 and 2% groups were negative. The mean weight gain was lower in the 2% group compared to controls. Relative kidney and live weights were increased in the 2% group, and relative liver weights were only increased in the 0.5% group. No adverse histopathological effects were observed The NOAEL can be considered to be 0.125 % (76 mg/kg-day) (Mellon Institute of Industrial Research, 1952; EU, 2006).

Male and female DW albino rats were given in their diet 0, 0.01, 0.05, 0.25 or 1.25% EGBE (corresponding to 7, 38, 188 or 919 mg/kg-day for males; and 0, 9, 41, 222, or 976 mg/kg-day for females) for three months. There was one death in the 1.25% group on day 73 of the study. Food consumption was decreased in the 1.25% group (both sexes). There was also a significant decrease of food consumption in the 0.25% males. Body

weight gain was significantly decreased in the 1.25 % animals (both sexes) and in the 0.25% males. Mean liver and kidney weight of males and females were significantly increased in the 1.25% group. The testes were atrophied in the 0.25 and 1.25% males. The NOAEL for this study can be considered to be 0.05%. (Mellon Institute of Industrial Research, 1963; reviewed in EU, 2006).

Rats (CR, COBS, CD-BR) were dosed by oral gavage with 0, 222, 443 or 885 mg/kg-day EBGE, five days/week for 6 weeks. In the high-dose animals, there was mortality (2/10) and significantly decreased body weight gain and food consumption (from days 3 to 20 of the study). Bloody urine, which persisted through the third week of treatment, was observed in the mid- and high-dose group; only one rat in the low-dose group had bloody urine. Other clinical signs in the mid- and high-dose groups were lethargy, unkempt hair coats, piloerection, rales, slight weakness and inactivity. In all treatment groups, there were significant effects on red blood cell (RBC) parameters, indicating hemolytic anemia. No effects were seen on white blood cells (WBC). There was a significant increase of alkaline phosphatase was seen from the mid-dose group. In the high-dose group, there was a significant increase of SGPT and a decrease of glucose. Absolute and relative spleen weights were increased for the middle and high dose of EGBE. Liver weights were slightly increased (only significant for relative weight) in the high-dose group. No effects were seen on testes weight (relative or absolute) at any dose group. Gross pathology showed only enlarged, dark spleens in the mid- and high-dose groups. Histopathological lesions were hyperkeratosis and acanthosis in the stomach epithelium in all treated animals. Hepatomegaly was also seen in 4 out of 10 animals of the high dose group. Hemosiderin deposition was seen in some animals (6/10 and 7/10 in the mid- and high-dose groups, respectively). Thymus atrophy was seen in one animal of the high-dose group. Congestion of the spleen was seen in all treated animals. Extramedulary hematopoiesis was reported for one animal in the high-dose group and hemosiderin deposit in the majority of animals of the mid- and high-dose group animals. The LOAEL for this study is considered to be 222 mg/kg-day based on effects in the spleen and on RBC parameters. A NOAEL was not obtained (Eastman Kodak, 1982).

Male and female F344/N rats were given in their drinking water 0, 750, 1,500, 3,000, 4,500 or 6,000 ppm EGBE for 13 weeks. Based on water consumption, the average daily intake was 0, 69, 129, 281, 367 or 452 mg/kg-day for males; and 0, 82, 151, 304, 363 or 470 mg/kg-day for females. Supplemental groups were included for hematology and clinical chemistry observations at weeks 1 and 3. There was no mortality and no clinical signs of toxicity. Reduced body weight gain was seen in the $\geq$4,500 ppm animals. There were reductions in drinking water consumption in the higher dose groups (both sexes), this being clearly concentration-related in females, from a mean of 18.8 mL/day in the control group to 10.7 mL/day in the 6,000 ppm group. A markedly macrocytic and mildly hypochromic anemia was observed at each time point and reticulocyte counts were moderately increased in weeks 1 and 13. For males there was a decrease in erythrocyte counts at all time points in the $\geq$3,000 ppm groups, while in females the decrease occurred in the $\geq$1,500 ppm groups. A consistent thrombocytopenia was observed at all time points in $\geq$4,500 ppm males and females; it also occurred in the 3,000 ppm females at week 13. The most consistent blood chemistry observation was an

increase in alkaline phosphatase, particularly in the high dose groups. This observation is consistent with mild cholestasis. Thymus weights were significantly reduced in 4,500 ppm males of the 4,500 ppm and the 6,000 ppm males and females. Other organ weight changes were found, but these appeared to be secondary to body weight gain reduction (spleen was not weighed). Histopathological effects were seen in the liver, spleen and bone marrow of both male and female rats. The liver changes were primarily centrilobular hepatocellular degeneration and centrilobular Kupffer cell pigmentation. These changes were present in the majority of dosed rats, but they were more prevalent in the $\geq$3,000 ppm animals and were slightly more severe in females. In addition, the cytoplasm of hepatocytes of treated rats was more eosinophilic and lacked the ampholytic-to-basophilic granularity typical of the controls. In the spleen there was an increase in hematopoiesis and deposition of hemosiderin. In bone marrow there was an hyperplasia characterized by an increase of hematopoietic cells and decrease in marrow fat cells. All of these lesions were present in the majority of dosed rats, but they were more prominent in the $\geq$3,000 ppm animals. Testis weights were unaffected by treatment, but the size of the uterus in the $\geq$4,500 ppm groups were reduced. Changes in uterine weight were considered by the authors to be secondary to the reduction in body weight gain rather than a direct effect of EGBE. Sperm concentration was slightly decreased in all treated males (not dose-related); all other sperm measurements were similar to controls. Estrous cycle length was unaffected by treatment, although the $\geq$4500 ppm females spent more time in diestrous than the other groups. This correlated with the smaller uterine size, which was attributed to a secondary consequence of reduced body weight gain. The LOAEL for this study is 750 ppm (69 and 82 mg/kg-day for males and females, respectively). A NOAEL was not obtained (NTP, 1993).

Male and female B6C3F$_1$ mice were given in their drinking water 0, 750, 1,500, 3,000, 4,500 or 6,000 ppm EGBE for 14 weeks. Based on water consumption, the average daily intake was estimated to be 0, 118, 223, 553, 676 or 694 mg/kg-day for males; and 0, 185, 370, 676, 861 or 1,306 mg/kg-day for females. There was no mortality and no significant clinical signs of toxicity. Reduction in body weight gain was seen in the $\geq$3,000 ppm males and females. Water consumption did not appear to be affected by treatment. Organ weight changes were considered secondary to body weight gain reduction. No treatment-related gross or microscopic lesions in male or female mice were observed. The NOAEL for this study is 223 and 370 mg/kg-day for males and females, respectively. However, this study did not include hematology measurements (NTP, 1993).

Genotoxicity

Below are the conclusions from the EU Risk Assessment Report on 2-butoxyethanol.

EGBE is not mutagenic in bacteria. One report showed a significant response in *S. typhimurium* strain TA97a (Hoflack *et al.*, 1995). This finding could not be substantiated by Gollapudi e*t al.* (1996). The metabolites butoxy aldehyde (BAL) and butoxy acetic acid (BAA) are also not mutagenic to bacteria. No mutagenic activity was observed in

two of three *in vitro* mammalian cell mutation assays; the other study, which was poorly reported, showed a positive finding at very high concentrations. The same study also reported a positive finding with a very high concentration of BAL, whereas another study showed not effects at slightly lower concentrations. No *in vitro* mammalian cell mutation assays have been conducted with BAA.

Inconsistent findings have been reported for SCE induction with EGBE. Inhibition of gap-junctional intercellular communication was reported in a single study with EGBE and its two major metabolites. A significant response was seen in a single assay for UDS induction with a technique that is now considered to be invalid.

EGBE has not been shown to induce chromosomal aberrations in a number of mammalian cell culture studies, or in one study with BAL or BAA. Weak aneugenic effects were seen in one study with EGBE and BAL, but not with BAA. *In vitro* studies with long exposure to BAL, and to a much less extent with EGBE itself, appear to induce micronuclei from aneuploidy rather than from chromosomal breakage.

There is no evidence for micronucleus induction in bone marrow cells or interaction with DNA in several organs of rats from *in vivo* exposure. The possibility of non-disjunction occurring and not being detected in these assays appears to be remote, because BAA produced no evidence of aneugenicity in vitro. BAA is rapidly formed *in vivo* and is by far the most prevalent blood metabolite of EGBE; thus, exposure of possible target cells to either EGBE or BAL at high concentrations is brief. Overall, the evidence suggests that EGBE does not pose a significant mutagenic potential *in vivo*.

Carcinogenicity

Male and female F344/N rats were exposed by inhalation to 0, 31.2, 62.5 or 125 ppm (0, 151, 302 or 604 mg/m^3) EGBE vapor for 6 hours/day, five days/week for 104 weeks (NTP, 2000). For hematological and bone marrow analyzes, additional groups of animals were exposed to 0, 62.5 or 125 ppm for evaluation at 3, 6 and 12 months; and to 31.2 ppm for 3 months (hematological examination only) and 6 months. Survival of exposed male and female rats was similar to the control animals, and no clinical signs were attributed to EGBE exposure. Body weights of male and female rats in the low- and mid-dose groups and the high-dose males were generally similar to the controls throughout the study. Body weights of the high-dose female rats were generally lower than those of the controls from week 17 until the end of the study. The incidence of benign or malignant pheochromocytoma (combined) of the adrenal medulla in females exposed to 125 ppm EGBE was not significantly increased compared to the chamber controls, but it did exceed the historical control range. There was only one malignant phaeochromocytoma, which occurred in the 125 ppm group. It was concluded that there was no evidence for carcinogenicity in male rats and equivocal evidence for carcinogenicity in female rats.

Male and female B6C3F$_1$ mice were exposed by inhalation to 0, 62.5, 125 or 250 ppm (0, 302, 604 or 1,208 mg/m^3) EGBE vapor for 6 hours/day, five days/week for 104 weeks (NTP, 2000). For hematological and bone marrow analyzes, additional groups of animals were exposed to 0, 62.5, 125 or 250 ppm for evaluation at 3, 6 and 12 months. Survival of male mice exposed to 125 or 250 ppm was significantly less than that of the controls, whereas survival in all other treated groups was similar to the controls. No clinical signs were attributed to EGBE. Body weights of exposed male mice were generally less than the controls during the last 25 weeks of the study. Body weights of the high-dose females were generally lower than the controls from week 30 until the end of the study, the difference being about 20% for much of that time. Body weights of the low- and mid-dose groups were generally lower than the controls from about week 60 until the end of the study. There was a positive trend in the incidences of forestomach squamous cell papilloma and squamous cell papilloma or carcinoma combined in female mice. The incidences were significantly increased in the 250 ppm group, in which the only squamous cell carcinoma occurred. These incidences exceeded the historical control range for female mice. There was no significant increase in the incidence of these neoplasms in male mice, but they did exceed the historical control range for male mice. Again, there was one squamous cell carcinoma, but in the 125 ppm group.

There was a positive trend in the incidence of hemangiosarcomas in male male mice, which was statistically significant in the 250 ppm group. The incidence at 250 ppm also exceeded the historical control range for this tumor in male mice. There was also a positive trend in the incidence of hepatocellular carcinomas, which was statistically significant in the 250 ppm group. There was, however, no change in the incidence of hepatocellular adenomas and carcinomas combined, because of a reduced incidence of hepatocellular adenomas in the treated groups. In female mice there was a single haemangiosarcoma, in the 62.5 ppm group, which was considered to be an incidental finding. Furthermore, the incidences of hepatocellular adenomas were reduced in the 125 and 250 ppm groups of female mice and there was no change in the incidence of hepatocellular carcinomas. The NOAEC for tumorigenicity in mice is 125 ppm, based on an increased incidence of hemangiosarcomas in males and squamous cell papillomas or carcinomas in females at 250 ppm.

Proposed Mode of Action (MOA) for Forestomach and Liver Hemangiosarcomas in Female and Male Mice from EGBE Exposure

The EU Risk Assessment Report (2006) evaluated the MOA for the forestomach and liver hemangiosarcomas in female and male mice and the relevancy of these tumors for human health risk assessment using the IPCS Human Relevance Framework.

I. Postulated Mode of Action for the Induction of Tumours of the Forestomach in Female Mice

"The proposed mechanism of action for production of tumours in the forestomach is the local generation, as well as accumulation of cytoxic metabolite(s) that induce a sustained, compensatory cell proliferation, neoplasia arising out of this proliferating cell population.

The neoplasia was mainly papillomas, a single squamous cell carcinoma arising in the highest dose group of female mice."

II. Postulated Mode of Action for the Induction of Hamangiosarcomas of the Liver in Male Mice

"The proposed mechanism of action for production of haemangiosarcomas of the liver is the deposition of haemosiderin in relevant cell-types, possibly including endothelial cells from which haemangiosarcomas arise, and the generation of cytotoxic reactive oxygen species that either induce genetic changes by this secondary mechanism or sustained cell proliferation within the endothelial target tissue, neoplasia arising out of this proliferating cell population."

III. Summary

"EGBE is carcinogenic in male mice, where it causes a low incidence of haemangiosarcomas, and female mice, where is causes an increased incidence of forestomach tumours. It is not carcinogenic in rats. Genotoxicity is not an important toxicological property of this chemical and it is unlikely that the low, variable and uncertainly defined genotoxic activity can be the cause of the carcinogenic responses. Hypotheses have been proposed and supported by experiment data in an attempt to explain the carcinogenic responses…In the case of forestomach tumors, the argument that they arise in a tissue subject to sustained abuse and consequent repair is clear. It is likely that this finding is in reality not sex specific but merely due to chance that the low level incidence in females rose above the level of statistical significance but it did not do so in males. In the case of the haemangiosarcomas, data from experiments with other chemicals show that mice are more susceptible to haemangiosarcoma development than are rats, and male mice are more sensitive than female mice, but the database in support of the hypothesis that life-long exposure of the liver to Kupffer cell pigmentation is a pre-requisite for an increase in liver haemangiosarcoma rates in male mice is small, after exclusion of doubtful examples. With the rejection of genotoxicity as a possible mechanism, strong evidence for a potential source of reactive oxygen species within the liver, and a mode of action where each step has at least some supporting data, it is reasonable to presume that these may play a role in the neoplasia."

"With regard to human relevance, the mechanism proposed for the induction of haemangiosarcomas strongly suggests that EGBE is not likely to be a carcinogenic hazard under conditions of normal handling and use, because human erythrocytes are demonstrably more resistant to haemolysis than are rodent erythrocytes. The mechanism proposed for the induction of forestomach tumours would also point to a lack of human relevance under conditions of normal handling and use. As stated recently (IARC, 2003), while people do not possess forestomachs, they do have comparable squamous epithelial tissues in the oral cavity and the upper two-thirds of the oesophagus. Thus, in principle, carcinogens targeting the forestomach squamous epithelium in rodents are relevant for man. However, the relevance for man is probably low for agents that have no demonstrable genotoxicity and that are solely carcinogenic for the forestomach squamous

epithelium in rodents after oral administration. Consequently, for these agents, the mode of carcinogenic action could be specific to the experimental animals (IARC, 2003). EGBE satisfies only some of these conditions. On the other hand, there are proposed mechanisms that are supported by experimental evidence to show how this chemical, even when inhaled, can accumulate in the forestomach contents, where it can remain for many hours to cause damage directly or after its metabolism to BAA."

"In conclusion, given the species and sex specificity of the neoplastic responses and the current evidence supporting the hypothesis that the more likely mechanism of action is based on haematotoxicity, then EGBE is unlikely to be a human carcinogen."

Reproductive Toxicity

Male and female Swiss CD-1 mice were given in their drinking water 0 0.5, 1.0 or 2.0 % EGBE (equivalent to daily intakes of 0, 720, 1340 and 2050 mg/kg-day) during a continuous breeding phase (CBP) with a 7-day pre-mating period and a 98-day cohabitation period (Morrissey *et al*., 1988,1989; Heindel *et al.*, 1990). There were significant adverse reproductive effects in the females at very high dose levels ($\geq$1,340 mg/kg) which also caused severe toxicity, including death. Under the conditions of the study, the NOAEL for reproductive toxicity of EGBE (fertility) was considered to be 720 mg/kg-day. For developmental toxicity, a NOAEL could not be derived. There was a very slight decrease in pup weight was observed at 720 mg/kg-day. No NOAEL or LOAEL can be determined for systemic parental toxicity because this kind of study is not designed to assess systemic toxicity although it is of note that there were effects (reduced fluid consumption) even at the lowest dose of 720 mg/kg-day.

There were no macroscopic nor microscopic effects on the reproductive organs in the repeated dose toxicity studies at doses which does not result in severe general toxicity.

Developmental Toxicity (Oral Studies Only)

A developmental toxicity study was conducted by oral gavage using Fischer 344 rats with the purpose of determining whether the exposure of pregnant rats to EGBE during critical periods of cardiovascular development adversely affected the structure of the fetal heart and great vessels. Pregnant rats were dosed on GD 9-11 with 0, 30, 100 or 200 mg/kg EGBE, with some animals sacrificed on GD 12 and others sacrificed on GD 20. Other group of pregnant rats were dosed on GD 11-13 with 0, 30, 100 or 300 mg/kg EGBE, with some animals sacrificed on GD 14 and the others sacrificed on GD 20. At doses of $\geq$100 mg/kg on GD 9-11 and GD 11-13, there was marked body weight reduction and/or weight gain, increased kidney and spleen weights, and severe hematotoxicity. The hematotoxicity was characterized by a large reduction in circulating red blood cells, hematocrit and hemoglobin, which occurred 24 hours post-treatment. The observed embryo/fetal effects included increased resorptions, non-live implants, and adversely affected implants per litter in the 200 mg/kg dose group of the GD 9 – 11 treated dams,

and decreased platelet count but no embryolethality in the 300 mg/kg dose group of the GD 11-13 treated dams. EGBE treatment did not increase malformations, including cardiovascular malformations. Increased fetal lethality did occur in the 200 mg/kg dose group when given during GD 9-11, but there were no increased malformations. Increased platelet count was also seen in the fetuses of the 300 mg/kg dose group given during GD 11-13. The maternal NOAEL for this study is 30 mg/kg-day. The developmental NOAEL is 100 mg/kg-day when EGBE is given on GD 9–11, and the NOAEL is 300 mg/kg-day when EGBE is given on GD 11–13 (Sleet *et al.*, 1991).

Pregnant CD-mice were dosed by oral gavage with 0, 350, 650, 1,000, 1,500 or 2,000 mg/kg EGBE during GD 8 to 14. Maternal toxicity was evident in the dams at dosed of ≥650 mg/kg. There were hemolytic effects (≥650 mg/kg) and mortality (≥1,500 mg/kg). At 1,000 and 1,500 mg/kg, increased resorption rates and numerically reduced number of viable fetuses were observed at 1,000 and 1,500 mg/kg. Cleft palates were seen in 4/43 fetuses (in one litter) at 1,000 mg/kg/day and 1/25 at 1,500 mg/kg. The NOAELs for maternal and developmental toxicity are 350 and 650 mg/kg-day, respectively (Wier *et al.*, 1987).

A subsequent reproduction study was conducted which followed a Chernoff modification study design with treatment of the pregnant mice at 650 or 1,000 mg/kg-day between GD 8 and 14; the animals were allowed to give birth and the offspring were observed until PND 22. Hemolytic effects and reduction in body weight were seen in the dams at 1,000 mg. There were no adverse developmental effects including pup growth or survival. The NOAELs for maternal and developmental toxicity are 650 and 1,000 mg/kg/day, respectively.

In another Chernoff assay, fifty mated CD-1 mice were dosed by oral gavage with 1,180 mg/kg-day EGBE (in corn oil) from GD 7 to 14, then allowed to litter and to rear pups to PND 3. Nineteen of the dams died (20%), maternal weight gain was reduced and there were only 24 viable litters (77 %) from the surviving dams compared with 97 % in the controls. There was no external malformations, pup survival to PND was unaffected, and there was no other evidence of developmental toxicity (Schuler *et al.*, 1984).

Key Study/Critical Effect for Screening Criteria

An oral RfD was derived by U.S. EPA (2010) based on the findings of the NTP chronic inhalation studies, the rationale being the limited oral database and because the critical endpoint, hemosiderin pigmentation, was more pronounced in the chronic inhalation study (NTP, 2000) versus the available subchronic oral study (NTP, 1993). The following information on the NTP chronic studies was obtained from IRIS:

"In this chronic study, animals were exposed to EGBE 6 hours/day, 5 days/week at concentrations of 0, 31, 62.5, and 125 ppm (0, 150, 302, and 604 mg/m^3) for groups of 50 F344/N rats and 0, 62.5, 125, and 250 ppm (0, 302, 604, and 1,208 mg/m^3) for groups of 50 B6C3F$_1$ mice. The researchers stated that the highest exposure was selected to

produce a 10-15% depression in hematologic indices. They reported that no effect on survival was observed in rats, but survival was statistically significantly decreased in male mice exposed to 125 or 250 ppm, compared with chamber controls (54, 52, and 78% respectively). Although statistics were not reported for mean body weights, the rats exposed to 31 and 62.5 ppm had similar mean body weights to the control rats. Mean body weights of the exposed mice were generally less than for controls, with females experiencing greater and earlier reductions. From week 17 to the end of the study, the mean body weights of 125 ppm female rats were generally less than those of controls. Non-neoplastic effects in rats included hyaline degeneration of the olfactory epithelium in males (13/48, 21/49, 23/49, 40/50) and females (13/50, 18/48, 28/50, 40/49) and Kupffer cell pigmentation in the livers of males (23/50, 30/50, 34/50, 42/50) and females (15/50, 19/50, 36/50, 47/50). The severity of the olfactory lesion was not affected by exposure. The Kupffer cell pigmentation is a result of hemosiderin accumulation and is a recognized secondary effect of the hemolytic activity of EGBE."

"Statistically significant effects observed in mice included forestomach ulcers and epithelial hyperplasia, hematopoietic cell proliferation and hemosiderin pigmentation in the spleen, Kupffer cell pigmentation in the livers, and bone marrow hyperplasia (males only). Hyaline degeneration of the olfactory epithelium (females only) was increased relative to chamber controls but was not statistically significant. As in the rats, the Kupffer cell pigmentation was considered a secondary effect of the hemolytic activity of EGBE. Bone marrow hyperplasia, hematopoietic cell proliferation, and hemosiderin pigmentation in the spleen were also attributed to the primary hemolytic effect; it was followed by regenerative hyperplasia of the hematopoietic tissue. The forestomach lesions did not appear to be related to the hemolytic effect of EGBE. Incidences of ulcer were significantly increased in all exposed female groups, as well as males exposed to 125 ppm. Incidences of epithelial hyperplasia, usually focal, were significantly increased in all exposed groups of males and females. The hyperplasia was often associated with ulceration, particularly in the females, and consisted of thickness of the stratified squamous epithelium and sometimes the keratinized layer of the forestomach. Ulceration consisted of a defect in the forestomach wall that penetrated the full thickness of the epithelium and frequently contained accumulations of inflammatory cells and debris."

"Using the same exposure levels described above, additional groups of rats (27/gender/exposure group) and mice (30/gender/exposure group) in the 2-year study were examined at 3, 6, and 12 months (8-10 animals/time point) for hematologic effects. Nine male and nine female rats were exposed to 31 ppm EGBE, specifically to evaluate hematology at 3 months and to receive a total evaluation at 6 months. Animals were continuously exposed, as described above, until their sacrifice at 3, 6, or 12 months. As in the 14-week study, inhalation of EGBE by both species resulted in the development of exposure-related hemolytic effects, inducing a responsive anemia. In rats, the anemia was persistent and did not progress or ameliorate in severity from 3 months to the final blood collection at 12 months. Statistically significant ($p < 0.05$) decreases in automated and manual hematocrit (Hct) values, hemoglobin (Hb) concentrations, and red blood cell (RBC) counts occurred at 3, 6, and 12 months in the 125 ppm female mice and the 250 ppm male and female mice. Statistically significant decreases in these same endpoints

were also observed in 62.5 ppm females at 6 months and in 125 ppm males at 6 and 12 months (decreases in Hct were observed only at 3 and 6 months). Mean cell volume (MCV) was increased in female mice at the highest duration (12 months) and exposure (250 ppm) levels. Reticulocyte counts were increased significantly in the 125 ppm females at 3 and 6 months and in the 125 ppm males at 6 months of exposure."

U.S. EPA used a route to route extrapolation from the NTP (2000) study for the derivation for the RfD. The dose metric used for animal-to-human and route-to-route (inhalation-to-oral) extrapolation for the derivation of the RfD is the area under the curve (AUC) of BAA at 12 months in arterial blood. This dose metric was used for dose-response modeling of chronic inhalation data to derive the point of departure (POD) of 133 µmol-hour/L, expressed as a BMDL based on animal data. The corresponding human BMDL was then back-calculated using the human PBPK model (Corley *et al.*, 1994; Corley *et al.*, 1997) to obtain an equivalent human oral drinking water dose ($BMDL_{HED}$) of 1.4 mg/kg-day. A simplifying assumption was used that the entire dose of drinking water EGBE was consumed over a 12-hour period each day.

U.S. EPA Oral Reference Dose (RfD) = 1.4/100 = 0.1 mg/kg/day

Drinking water guidance value = 0.5 ppm

Toxicity Profile

Ethanol
(CAS No. 64-17-5)

Ethanol has been reviewed in the OECD-SIDS program (OECD, 2004a,b).

Acute Toxicity

Ethanol has a low order of acute toxicity by all routes of exposure. The lowest well-conducted acute oral LD_{50} value is 8,300 mg/kg in mice, and an inhalation 1-hour LC_{50} value of >60,000 ppm (114,000 mg/m^3) in mice.

Irritation

Ethanol is a moderate eye irritant but it is not a skin irritant.

Sensitization

Ethanol is not a sensitizer.

Repeated Dose Toxicity

There are numerous repeat dose toxicity studies on ethanol by the oral route. Many of these studies were designed to increase our understanding of the risks associated with alcoholic beverages. Thus, these studies were carried out by the oral route and at high doses. The selected studies were considered appropriate for risk assessment purposes.

In a 90-day study, male and female Sprague-Dawley rats were fed a diet containing 0, 1, 2, 3, 4, 5 or 10% ethanol. The 2% dose was calculated to be equivalent to 2,400 mg/kg/day. There were no deaths and no clinical signs of noted. Weight gain throughout the study was unaffected by treatment, but the final weights decreased with dose. Food and water consumption in the 10% group was reduced relative to controls. There was no treatment-related effect on serum liver enzymes and kidney clinical chemistry findings were minimal. In the liver, centrilobular steatosis increased in severity with dose as did the frequency and severity of Mallory bodies (hyaline) and acidophilic degeneration and necrosis. Most liver findings were absent or mild at 2% ethanol but became more significant at $\geq$3%. The NOAEL for this study has been established to at 2% (2,400 mg/kg/day).

In an NTP 90-day study, F344/N rats and $B6C3F_1$ mice were given in their drinking water 0 or 5% ethanol in drinking water. Based on the water consumption data in the

study and averaged body weights over the exposure period, this equated to doses of at least 4,000 mg/kg in rats and 7.500 mg/kg in mice. Male rats showed minor changes to organ weights and hematology and clinical chemistry parameters (these were not considered to be adverse changes); female rats showed minor clinical chemistry changes and increased length of estrus cycle, as well as liver nodules. The male mice showed increased organ weights, fatty changes to the liver, and a decrease in sperm concentration.

In the NTP two-year bioassay, B6C3F$_1$ mice were given in their drinking 0, 2.5% and 5% ethanol Concentrations of 2.5% and 5% ethanol resulted in average daily consumption of approximately 100 and 180 mg ethanol for males and 80 and 155 mg for females. There was a marginal exposure-related increase in survival of the males, but no effect on the survival of the females. Water consumption was reduced with increasing concentrations of ethanol which was more marked in males than females. No further information was given on non-neoplastic effects.

Genotoxicity

The balance of evidence is that ethanol is not genotoxic. Negative results from a number of bacterial mutation assays appear to be reliable. Of the mammalian cell mutation assays a weak mutagenic effect in mouse lymphoma cells occurred only at very high ethanol concentrations. *In vivo* tests for chromosome aberrations in both rats and Chinese hamsters have given negative results. There is very little evidence to suggest that ethanol is genotoxic in somatic cells and it may have a very limited capacity to induce genetic changes *in vivo* but under very specific circumstances and at very high doses achievable in humans only by deliberate oral ingestion.

Carcinogenicity

Evidence of the carcinogenicity of ethanol is confined to epidemiological studies assessing the impact of alcoholic beverage consumption. These do not indicate any such hazard exists from potential exposure to ethanol in the work place or from the use of ethanol in consumer products.

Reproductive/Developmental Toxicity

The lowest reported NOAEL for fertility by the oral route was 2,000 mg/kg in rats, equivalent to a blood alcohol concentration of 1,320 mg/L, although this was based on a significant increase in the number of small pups rather than a direct effect on fertility; such direct effects are not seen until much higher doses. Many studies exist examining the developmental end point for ethanol. However, most use very high doses and few are individually robust enough to allow a NOAEL to be established. However, the collective weight of evidence is that the NOAEL for developmental effects in animals is high,

typically >6,400mg/kg, compared to maternally toxic effects at 3,600 mg/kg. The potential for reproductive and developmental toxicity exists in humans from deliberate over-consumption of ethanol. Blood ethanol concentrations resulting from ethanol exposure by any other route are unlikely to produce reproductive or developmental effects.

Key Study/Critical Effect for Screening Criteria

The lowest reported NOAEL is approximately 2,400 mg/kg/day from a 90-day dietary study with rats.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 2,400/1,000 = 2.4 mg/kg/day

Drinking water guidance value = 8.4 ppm

Toxicity Profile

Guar Gum
(CAS No. 9000-30-0)

Guar gum (CAS No. 9000-30-0) is the milled endosperm of the leguminous plant *Cyanopsis tetragonolobus*. Structurally, it is a galactomannan consisting of a main chain of D-mannose with a side chain of D-galactose at approximately every second mannose unit. The mannose units are β-(l-4) linked, and the single D-galactose units are joined to the main chain by α-(1-6) linkages. The estimated molecular weight of guar gum cranges from 200,000 to 300,000 daltons (Glickman, 1969).

Guar gum is approved for use as a food additive by the U.S. Food and Drug Administration and is on the list of substances "generally recognized as safe" (CFR 1974).

Acute Toxicity

The oral LD_{50} is 8,100 mg/kg for mice and 9,400 mg/kg for rats (Bailey and Morgareidge, 1948).

Irritation

No data were found.

Sensitization

There are reports of respiratory sensitization in workers exposed occupationally to guar gum dusts (Maio, 1986).

Repeat Dose Toxicity Studies

F344 rats and B6C3F_1 mice were given diets containing 0, 6,300, 12,500, 25,000, 50,000 or 100,000 ppm guar gum for 13 weeks (NTP, 1982). Mean body weights were decreased in male rats (100,000 ppm group) and in female mice (50,000 and 100,000 ppm). A dose-related decrease in feed consumption was observed for male and female rats; male and female mice were comparable or higher than that of controls. There were no compound-related clinical signs or histopathological effects.

F344 rats and B6C3F_1 mice were given diets containing 0, 25,000 ppm or 50,000 ppm guar gum for 103 weeks (NTP, 1982). Mean body weights of the high-dose females were

lower than those of the controls after week 20 for mice and week 40 for rats. No compound-related clinical signs or adverse effects on survival were observed. Feed consumption by dosed rats and mice of either sex was lower than that of controls. There were no non-neoplastic histopathological effects in either rats or mice that were treatment-related.

Genotoxicity

Guar gum was not mutagenic to *Salmonella typhimurium* TA 1530 or G-46 when tested without metabolic activation; however, it was mutagenic to *Saccharomyces cerevisiae* D-3 (Green, 1977). Guar gum also was reported to cause chromosomal aberrations in human embryonic lung cells WI-38 (Green, 1977). No *in vivo* genotoxicity studies have been conducted on guar gum.

Carcinogenicity

F344 rats and B6C3F_1 mice were given diets containing 0, 25,000 ppm or 50,000 ppm guar gum for 103 weeks (NTP, 1982). There were increased incidences of adenomas of the pituitary in male rats and pheochromocytomas of the adrenal in female rats that were statistically significant, but these differences were considered to be unrelated to guar gum administration. When pituitary adenomas or carcinomas and when pheochromocytomas or malignant pheochromocytomas are combined, the statistical differences disappear. Hepatocellular carcinomas occurred in treated male mice at incidences that were significantly lower than that in controls. The combined incidence of male mice with either hepatocellular adenomas or carcinomas was also significantly lower in the high-dose group. It was concluded that under conditions of this bioassay, guar gum was not carcinogenic for F344 rats or B6C3F_1 mice.

Reproductive Toxicity

No data were found.

Developmental Toxicity

Female rabbits were given daily (6 hours/day) dermal administration of 0, 2, 10 and 50 mg/kg guar gum during gestational days 6 through 18 (IRDC, 1988). Mortalities included 2 deaths at 50 mg/kg and 1 death at 10 mg/kg. A single animal was killed in extremis. A dose-related increase in dermal irritation (including erythema, edema, and desquamation) was observed in animals receiving 10 and 50 mg/kg. The number of early resorptions was significantly increased and the number of viable fetuses was correspondingly decreased at 50 mg/kg/day ($p<0.05$). The frequency of fetal malformations and variations in the treated groups was comparable to that of the control

group at all dose levels. The NOEL for this study is 2 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The key studies for the determination of a drinking water guidance value is the NTP two-year chronic bioassays. The LOAELs are based on decreased mean body weights in female mice and rats fed 50,000 ppm guar gum in diet for 103 weeks. The NOAELs for these studies are 25,000 ppm guar gum.

Rat: NOAEL (mg/kg/day) = 25,000 ppm * 0.05 = 1,250 mg/kg/day

Mouse: NOAEL (mg/kg/day) = 25,000 ppm * 0.13 = 3,250 mg/kg/day

Where 0.05 and 0.13 are the fraction of body weight that rats and mice, respectively, consume per day as food (U.S. EPA).

The lowest NOAEL of 1,250 mg/kg/day for the rat will be used to derive a drinking water guidance value.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 1,250/100 = 12.5 mg/kg/day

Drinking water guideline = 44 ppm

Toxicity Profile

Hydrochloric acid
(CAS No. 7647-01-0)

Hydrochloric acid has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Hydrochloric acid (HCl) or hydrogen chloride is readily dissociated in water into hydrated protons and chloride ion.

Acute Toxicity

The oral LD_{50} value of hydrogen chloride is reported to be 238 to 277 mg/kg for female rats (Hoechst AG, 1966), and 900 mg/kg for rabbits (Loewy and Munzer, 1923). The lethal dose by dermal exposure is >5,010 mg/kg for rabbits (Monsanto, 1976). The LC_{50} values for HCl are reported to be 23.7 - 60.9 mg/L/5min, 5.7- 7.0 mg/L/30min and 4.2 4.7 mg/L/60min for rats; and 20.9 mg/L/5min, 3.9 mg/L/30min and 1.7 mg/L/60min for mice (Darmer *et al.*, 1974; Hartzell *et al.*, 1990; MacEwean *et al.*, 1974).

Irritation

Concentrations >3.3% cause skin irritation, and concentrations >17% cause corrosion in animal studies (OECD, 2002a,b). An aqueous solution (4%) of hydrogen chloride was slightly irritating (Agner and Serup, 1988), and a 10% solution was determined to be 'Irritating to skin' for the EU Dangerous Preparations Directive, in human volunteer experiments (York *et al.*, 1996).

0.1 mL of 10% aqueous solution of HCl was highly irritating to the eyes of rabbits (Jacobs, 1992); 0.03 mL or more of 5% HCl was corrosive to the eyes of rabbits (Griffith *et al.*, 1980); 0.1 mL of a 3.3% aqueous solution of HCL was slightly irritating the eyes of rabbits (Hoechst AG, 1966); and 0.1 mL of a 0.33% aqueous solution of HCl was not irritating to the eyes of rabbits. (Hoechst AG, 1966).

Sensitization

Hydrogen chloride is not a skin sensitizer to guinea pigs and humans (Gad *et al.*, 1986).

Repeated Dose Toxicity

Rats were fed diets containing 280 to 1,250 mmol/kg hydrochloric acid (10.2 to 45.6 mg/kg) for 7-12 weeks. There was increased water intake in all treated groups. All

animals fed diet containing 937 mmol/kg and above for 9 weeks, and half of the animals fed diet containing 900 mmol/kg for 12 weeks died. Also at doses ≥937 mmol/kg, there was decreased body weight, food consumption, blood pH, femur length, rate of ash in bone (Upotn and L'Estrange, 1977). In another study with rats, hydrochloric acid was administered via drinking water at pH 2-3 (study duration not provided). Decreased protein levels in urine and decreased urine volumes were observed in the treatment groups (Clausing and Gottschalk, 1989).

Genotoxicity

While consistent negative results have been obtained in the bacterial systems, positive results have been obtained in the non-bacterial systems (OECD, 2002a,b). The positive results were observed at high concentrations, but they were considered to be artifacts due to the low pH. Positive results were obtained in a sex-linked recessive lethal study with *D. melanogaster*; only one dose level was tested (Stumm-Tegethoff, 1966) There are no mammalian studies on *in vivo* mutagenicity with hydrogen chloride

Carcinogenicity (Oral Studies only)

A ten-month study has been conducted using mice (Dyer *et al.*, 1946). Because the methods such as strain used, duration and dose of administration, presence of co-administration substance, were not appropriate, it cannot be used for the assessment of carcinogenicity of hydrochloric acid.

Reproductive Toxicity

No reliable studies were identified by the oral route.

Developmental Toxicity

No reliable studies were identified by the oral route.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for pH may apply to hydrochloric acid.

Toxicity Profile

2-Propanol or Isopopranol
(CAS No. 67-63-0)

Acute Toxicity

The acute oral LD_{50} has been reported as 4,700 mg/kg, 5,300 mg/kg, 5,500 mg/kg, and 5,8400 mg/kg in rats; 4,500 mg/kg in mice; and 5,030 mg/kg, 7,800 mg/kg, and 7,900 mg/kg in rabbits (31, 272, 274, 275, 144, 35 Kimura et al., 1971; WHO, 1990; Smyth and Carpenter, 1948; Lehman and Chase, 1994; Munch and Schwartze, 1925; Munch, 1972). The acute dermal LD_{50} in rabbits has been reported to be 12,900 mg/kg (Smyth and Carpenter, 1948). The acute inhalation 8-h LC_{50} in rats was 19,000 ppm in females and 22,500 ppm in males (Laham *et al.*, 1980). Exposure of rats to 16,000 ppm for 8 h resulted in four deaths out of six animals (Smyth and Carpenter, 1948).

Irritation

Isopropanol applied to the intact or abraded skin of rabbits and guinea pigs produced negligible irritation (Nixon *et al.*, 1975). Liquid isopropanol is moderately irritating to the eyes of rabbits (Griffith *et al.*, 1980; WHO, 1990). Isopropanol produced little irritation when tested on the skin of six human subjects (Bevan, 2012).

Sensitization

There have been reports of isolated cases of dermal irritation and/or skin sensitization (Bevan, 2012). Except for three case reports, the positive reactions were observed on patch testing patients with contact dermatitis due to ethanol. These patients also had a positive reaction to ethanol.

Repeated Dose Toxicity (Oral Studies only)

In a drinking water study, rats ingested 0.5 to 10% of isopropanol for 27 weeks and showed decreased body weight gain but no gross or microscopic tissue abnormalities (Lehman and Chase, 1975). Increased formation of hyaline droplets in the proximal tubules was reported in male rats given 1–4% isopropanol in drinking water for 12 weeks (Pilegaard and Ladefoged, 1993). In another study, daily application of a 50% solution to the heads of rats for 187 days produced no apparent injury to the skin (Boughton, 1944). Isopropanol was administered in drinking water to three dogs for 7 months. The alcohol concentration was 4% from the end of the first month until the conclusion of the experiment. Tolerance to the alcohol developed as manifested by an increased degree of neuromuscular coordination at similar blood levels in habituated versus control animals

and by increased elimination of the alcohol. The only significant histopathological changes were noted in the kidneys of one dog that died (Lehman *et al.*, 1945).

Genotoxicity

All genotoxicity assays conducted so far with isopropanol have been negative (OECD, 1997a,b; Bevan, 2012). Isopropanol was not mutagenic in the *Salmonella* microsomal assay using the spot test, in strains TA98, TA100, TA1535, and TA1537 with and without S9 from the livers of Aroclor-induced rats (Abbondandolo *et al.*, 1980). Isopropanol was not mutagenic in *Salmonella* strains TA97, TA98, TA100, TA102, TA104, TA1535, TA1537, and TA1538 with and without metabolic activation, when tested using a plate-incorporation modification of this assay (Zeiger *et al.*, 1992).

Isopropanol was inactive in mutagenicity tests in *Neurospora crassa* (Brockman *et al.*, 1984) and isopropanol did not enhance adenovirus (SA7) transformation using Syrian hamster embryo cells (Heidelberger *et al.*, 1983). Isopropanol was inactive in a sister chromatid exchange assay with and without S9 metabolic activation (von der Hude *et al.*, 1987). Isopropanol was inactive in an *in vitro* CHO/HGPRT gene mutation assay and in an *in vivo* bone marrow micronucleus assay in mice (Kapp, Jr. *et al.*, 1993).

Carcinogenicity

No carcinogenicity studies have been conducted by the oral route.

CD-1 mice were exposed by inhalation to 0, 500, 2500, or 5000 ppm of isopropanol vapor for 6 h/day, 5 days/week for 18 months. An additional group of mice (all exposure levels) were assigned to a recovery group which were exposed to isopropanol for 12 months and then retained until study termination at 18 months. There was no increased frequency of neoplastic lesions in any of the isopropanol-exposed animals. Nonneoplastic lesions were limited to the testes (males) and the kidney. In the testes, enlargement of the seminal vesicles occurred in the absence of associated inflammatory or degenerative changes. The kidney effects included tubular proteinosis and/or tubular dilatation. The incidence of testicular and kidney effects was not increased in the isopropanol-exposed recovery animals (Burleigh-Flayer *et al.*, 1997).

Fischer 344 rats were exposed to 0, 500, 2500, or 5000 ppm of isopropanol vapor for 6 h/day, 5 days/week for 24 months. The mortality rates for all male rats were 82, 83, 91, and 100% for the 0-, 500-, 2500-, and 5000-ppm groups, respectively. The corresponding values for the female rats were 54, 48, 55, and 69%. The main cause of death for the 5000-ppm rats (both sexes), as well as for much of the mortality of the 2500-ppm male rats, was chronic progressive nephropathy. Isopropanol exposure resulted in impaired kidney function, as indicated by various urine chemistry changes in male (2500- and 5000-ppm) and female (5000-ppm) rats. Animals in these groups also exhibited histopathological effects in the kidneys which appeared to be an exacerbated form of

chronic progressive nephropathy. The only neoplastic lesion noted was increased interstitial (Leydig) cell adenomas in male rats. The frequency of these tumors, although elevated above the control animals, was within the historical control range of the testing facility and within the range reported for control animals from the National Toxicology Program carcinogenicity studies (Burleigh-Flayer *et al.*, 1997).

The carcinogenic potential of isopropanol was evaluated via inhalation using three strains of mice. Male mice were exposed to 7.5 ppm of isopropanol for 3 to 7 h/day, 5 days/week for 5 to 8 months. Animals were killed at either 8 or 12 months. There was no significant increase in the number of lung tumors observed. Similarly, no increases in lung tumors were observed in the same strains of mice that received subcutaneous injections of isopropanol once weekly for 20 to 40 weeks (Weil *et al.*, 1952).

Reproductive Toxicity

In a two-generation reproductive toxicity study, Sprague–Dawley rats were dosed by oral gavage with 0, 100, 500, or 1,000 mg/kg isopropanol. There were seven parental deaths that were considered treatment-related: two high-dose F_0 females, two F_1 high-dose females, one mid-dose F_0 female, and two low-dose F_1 males. Lactation body weight gain was increased in the 500- and 1000-mg/kg females in both generations, and liver and kidney weights were increased in the 500- and 1,000-mg/kg groups in both sexes. Centrilobular hepatocyte hypertrophy was noted in some 1,000 mg/kg F_1 males. There were some kidney effects in the 500- and 1000-mg/kg F_0 males and in all treated F_1 male rats. The kidney effects were characterized by an increased number of hyaline droplets in the convoluted proximal tubular cells, epithelial degeneration and hyperplasia, and proteinaceous casts. Increased mortality occurred in the high-dose F_1 offspring during the early postnatal period; no other clinical signs of toxicity were observed in the offspring from either generation. Offspring body weight, however, in the 1,000-mg/kg group was reduced during the early postnatal period. There was significant mortality in the F_1 weanlings (18/70) before the selection of the F_1 adults. A statistically significant reduction was observed in the F_1 male mating index of the 1,000-mg/kg group (73 versus 97% in the controls). There were no other treatment-related effects on reproduction, including fertility and gestational indices, or histopathology of the reproductive organs (Bevan *et al.*, 1995). A benchmark dose level of 420 mg/kg/day (lower bound on dose associated with a 5% response rate for the decrease in the male mating index was calculated (Allen *et al.*, 1998).

In a one-generation reproductive/embryotoxicity study, male and female Wistar rats were given 0, 0.5%, 1.0% or 2.0% isopropanol in their drinking water. The calculated intakes for males were 383, 686 and 1107 mg/kg-day (pre-mating) and 347, 625 and 1030 mg/kg-day (18 weeks of treatment). The calculated intakes for females were 456, 835 and 1206 mg/kg-day (premating); 668, 1330 and 1902 mg/kg-day (gestation); and 1053, 1948 and 2768 mg/kg-day (postpartum). An immediate, statistically significant dose-dependent decrease occurred in water intake in the male rats. Intake was reduced ~5-14% (1% group; premating period) and ~30% (2% group; days 7-11 to end of study).

Overall mean feed consumption was significantly lower in treated versus control animals. Male body weights (2% only) were reduced throughout the study. Water consumption was initially reduced in the 1% and 2% females, but the 2% group recovered to only ~70% of the control values (premating); it continued to be reduced during the gestation and lactation period. Mean maternal body weights were reduced (all treated groups) at the start of gestation, with partial recovery during the gestation period except for the 2% group. Overall weight gain during gestation in these groups were similar to the controls. Following parturition from PND 4 onward, the 2% dams had significantly lower body weights. There were no infertile males in any group, and no treatment-related effect on female fertility or on length of gestation. The number of pups/litter on GD 1 was reduced in the 2% group; because it was not replicated in the embryotoxicity portion, an increase in pup mortality during partuition or GD 0, followed by cannibalism of the dead pups by the dam was suggested. No macroscopic abnormalities were seen in females; nor was there any treatment-related histopathological changes seen in the reproductive tissue in the 2% parental animals. Absolute kidney weight and relative kidney, liver, and spleen weights were increased in the 2% F0 males; increased absolute liver and kidney weights and relative liver weights in the 2% F0 females. In the embryotoxicity portion, there was a statistically significant increase in the total number of preimplantation losses in the 2% animals. Whole body edema was seen in 40% of the fetuses in 3/8 litters in the 2% group. No macroscopic abnormalities of the viscera of these fetuses were detected, and the incidence of edema was not related to gender. In the one-generation portion, postnatal pup survival and in the average pup weight (by PND 7) were decreased in the 2% group. F1 generation animals of both sexes showed increased relative liver weights at all dose levels, and the 2% males had higher relative kidney weights. A slight but significant decrease in absolute brain weight and increase in relative empty cecum weights in both sexes of the 2% F1 generation group. No treatment-related gross abnormalities were observed in the F1 generation animals at necropsy (BIBRA, 1988).

The effects of isopropanol (2.5% in drinking water) on the reproduction and growth of rats was assessed in a multigenerational study. No reproductive toxicity was observed (Lehman *et al.*, 1945).

Isopropanol was administerd as a 3% solution in drinking water to Wistar rats. Reduced parental body weight gain, food, and water consumption was observed in the treated animals compared with the controls. Fertility, litter size, and pup weights at postnatal days 4 and 21 were reduced in treated animals compared with the controls. In the second generation, the isopropanol concentration was reduced to 2%, and there were essentially no effects (Gallo *et al.*, 1977).

Developmental Toxicity

Isopropanol was given at concentrations of 0, 0.5%, 1.25% or 2.5% in the drinking water to female Wistar rats on GD 6 to 16. The calculated intakes of isopropanol during GD 6-16 were 596, 1242 and 1605 mg/kg/day. There was an immediate reduction in water intake in the 2.5% dose group, and this was statistically significant throughout the

treatment period when compared to controls. A smaller reduction in water intake was also seen in the 1.25% females (statistically significant during GD 6-9), with no change in the 0.5% females. Palatability of the drinking water may have been the problem since water intake significantly increased the first day following the end of the treatment period for all dose groups. Feed consumption patterns paralleled the water consumption during and after treatment in the mid- and high-dose groups. Overall, mean body weights of the 2.5% females were lower than the controls from GD 7 to termination. Effects on weight gain in the 0.5% and 1.25% females were limited to a failure to gain weight during the first (0.5%) and second (1.25%) day of treatment. There were no treatment-related effects in postimplantation loss, mean number of implantation sites or live fetuses. There was a slight dose-dependent decrease in mean litter weight and a significant decrease in mean fetal weight in the 1.25% and 2.5% groups. A statistically significant increase in variations was observed, indicative of a lower degree of ossification in the treated animals There was a dose-dependent decrease in the number of fetuses with the 4^{th} sacral arch and a dose-dependent increase in the number of fetuses with less than 2 caudal arches. The sternum also showed reduced ossification because there were increased numbers of fetuses with small, absent, or incompletely ossified sternebrae (BIBRA, 1987).

In a rat developmental study, female Sprague–Dawley rats were dosed by oral gavage with either 0, 400, 800, or 1200 mg/kg of isopropanol during gestational days 6 to 15. Two dams (8%) died at 1200 mg/kg and one dam (4%) died at 800 mg/kg. At 1200 mg/kg, maternal body weights were reduced throughout gestation (GS 0-20; 89.9% of control value), associated with reduced gravid uterine weight. There were no other treatment-related effects on the dams. Fetal body weights per litter were also significantly reduced at the 800 and 1200 mg/kg dose levels, but there were no teratogenic effects. There were no adverse maternal or developmental effects at 400 mg/kg (Tyl *et al.*, 1994).

In a rabbit developmental study, female New Zealand white rabbits were dosed by oral gavage with either 0, 120, 240, or 480 mg/kg of isopropanol during gestational days 6 to 18. At 480 mg/kg, isopropanol was unexpectedly toxic to pregnant female rabbits, resulting in the deaths of four does (26%). Maternal body weights were significantly reduced during treatment (gestational days 6–18) and were associated with reduced maternal food consumption during this period. Profound clinical signs were noted at 480 mg/kg and included flushed and/or warm ears, cyanosis, lethargy, and labored respiration. No adverse maternal effects were noted at 120 or 240 mg/kg. There were no developmental or teratogenic effects at any dose tested (Tyl *et al.*, 1994).

Isopropanol was given by oral gavage to Sprague–Dawley rats from gestational days 6 to 21 in doses of 0, 200, 700, or 1200 mg/kg. The dams were allowed to deliver, litters were culled on postnatal day (PND) 4, pups were weaned on PND 22, and their dams were killed. Weaned pups were assessed for day of testes descent or vaginal opening, motor activity, auditory startle, and active avoidance. The pups were killed on PND 68. Some of the pups were taken from each dose group and were perfused in situ for pathological examination of the central nervous system. There were no biologically significant findings in the behavioral tests, no changes in organ weights, and no pathological

findings of note. Thus, there was no evidence of developmental neurotoxicity from isopropanol exposure (Bates *et al.*, 1994).

Key Study/Critical Effect for Screening Criteria

The benchmark dose level of 420 mg/kg/day from the two-generation reproductive toxicity study will be used to derive a drinking water guidance value for 2-propanol.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral Reference Dose = 420/100 = 4 mg/kg/day

Toxicity Profile

Magnesium chloride
(CAS No. 7786-30-3)

Acute Toxicity

The oral LD_{50} of magnesium chloride hexahydrate in rats is >2,000 mg/kg. The dermal LD_{50} of magnesium chloride hexahydrate in rats is >2,000 mg/kg.

Irritation

Magnesium chloride hexahydrate was applied topically to the EPISKIN-SMätissue for 15 min followed by a 42 hour post-incubation period and immediate determination of cytotoxic effects via MTT reduction assay. The test item showed no irritant effects.

Single ocular instillation of magnesium chloride hexahydrate to rabbits at a dose of 0.1 g produced irritant effects, which were fully reversible within 6, 4 and 2 days post-instillation in animal no. 1, 2 and 3, respectively. Based on these findings, magnesium chloride hexahydrate is not an eye irritant.

Sensitization

Magnesium chloride hexahydrate was not a skin sensitizer when tested in guinea pigs.

Repeated Dose Toxicity

In an OECD 422 study, Wistar rats at dosages of 250, 500 and 1,000 mg/kg magnesium chloride hexahydrate revealed no major toxicological findings. The cause of death of animals during the conduct of the study could not be determined (a plausible cause may be gavage error or regurgitation). The NOAEL for this study is 1,000 mg/kg/day.

Groups of 50 male and 50 female $B6C3F_1$ mice were given magnesium hexahydrate at dose levels of 0, 0.5% and 2% in the diet for 96 weeks, after which all animals received the control diet for 8 weeks and were then necropsied. In the 2% females, a decrease in body weight was observed. However, survival rates did not differ between the treatment and control groups for males or females and clinical signs and urinary, hematological or serum clinical chemistry parameters showed no treatment-related effects. Therefore, this change was considered not to be of biological significance. The NOAEL for female and male mice was 2% in feed, which corresponded to 3,930 and 2,810 mg/kg/day, respectively.

Genotoxicity

Magnesium chloride was not genotoxic in the *in vitro* mouse lymphoma assay and in the *in vitro* chromosomal aberration assay using human lymphocytes.

Carcinogenicity

Male and female $B6C3F_1$ mice were given in their fed 0, 0.5% or 2% magnesium chloride hexahydrate for 96 weeks, after which all animals received the control diet for 8 weesk and were then necropsied. Tumors were mainly found in the skin/subcutis, liver and lymphatic system. With the exception of a significant decrease in the incidence of liver tumors among the 2% males, there were no differences in the tumor incidences between the treated and control animals.

Reproductive/Developmental Toxicity

In an OECD 422 study, Wistar rats at dosages of 0, 250, 500 or 1,000 mg/kg showed no treatment-related reproductive or developmental effects. The NOAEL for this study is 1,000 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for chloride may apply to magnesium chloride.

Reference

ECHA REACH database: http://apps.echa.europa.eu/registered/registered-sub.aspx

Toxicity Profile

Magnesium nitrate
(CAS No. 10377-60-3)

Acute Toxicity

The acute oral LD_{50} in rats is >5,000 mg/kg.

Irritation

No studies are available.

Sensitization

Magnesium nitrate is not a skin sensitizer based on results of a Local Lymph Node Assay (LLNA).

Repeat Dose Toxicity Studies

No studies are available.

Genotoxicity

Magnesium nitrate hexahydrate is not mutagenic in the *Salmonella typhimurium* reverse mutation assay and in the *Escherichia coli* reverse mutation assay.

Carcinogenicity

No data are available.

Reproductive Toxicity

No data are available.

Developmental Toxicity

No data are available.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guidance value for nitrates may apply to magnesium nitrate.

Reference

ECHA REACH database: http://apps.echa.europa.eu/registered/registered-sub.aspx

Toxicity Profile

Polypropylene glycol
(CAS No. 25322-69-4)

Acute Toxicity

Acute oral toxicity studies on PPGs of various molecular weights (300-3,900) have indicated LD_{50} values (rats) ranging from 500 to >40,000 mg/kg. In acute dermal toxicity studies, doses of PPG 1025 (20 ml/kg) and PPG 2025 (20 ml/kg) did not cause death to rabbits. Two of five rabbits dosed with 20 ml/kg PPG 425 and one of five dosed with 10 ml/kg PPG 425 died.

Irritation

Skin irritation was not noted after PPG 425, PPG 1025, or PPG 2025 was applied once to the skin of rabbits or when applied a total of eight times to the same area within 4 h. PPGs 425, 1025, and 2025 were classified as harmless agents in rabbits in another ocular irritation study; PPG 1200 induced slight, transient ocular irritation in an albino rabbit.

Sensitization

Neither skin irritation nor sensitization reactions were observed in 300 subjects who received continuous and repeated dermal applications of undiluted PPG 2000.

Repeated Dose Toxicity

PPG 2000 was administered to rats over a period of 100 days. Concentrations of 0.1, 0.3, 1.0, and 3.0% were administered in oral doses of 50 to 1,500 mg/kg/day. There were no adverse effects noted at concentrations of 0.1 to 1.0%. Slight decreases in growth were observed after the administration of 3% PPG 2000.

In a 90-day study, PPG 2000 was administered orally to rats in doses ranging from 275 to 501 mg/kg/day. There was no evidence of adverse histopathologic, hematologic, or clinical chemistry effects in any of the animals tested. Body weight effects (not specified) were noted at the highest dose tested. Similar results were reported for dogs that received doses of PPG 2000 ranging from 526 to 810 mg/kg/day.

PPG 1200 was fed to three groups of four pure bred beagle dogs for 90 days. Each group consisted of two male and two female dogs. The three groups ingested PPG 1200 at concentrations of 0.1, 0.3, and 1.0 % in the diet, respectively; six beagles in the control group were fed diets without PPG. At the highest “no effect level” (0.3%), average daily

consumption doses were 79 and 99 mg/kg for two male dogs and 90 and 123mg/kg for two female dogs. Data based on the following analyses did not indicate adverse effects at any of the concentrations tested: demeanor, feed consumption, hematologic parameters, clinical chemistry determinations, urinalysis, organ weights, organ/body weight and organ/brain weight ratios, or gross and microscopic examination of tissues and organs. Similar results were reported when three groups of 50 rats were dosed with 0.1, 0.3, and 1.0% PPG 1200, respectively, according to the same procedure.

PPG 750 was administered to rats over a period of 100 days. Concentrations of 0.1 and 1% were administered at doses of 50 and 500 mg/kg/day. PPG 750 (0.1%) did not induce any adverse effects. However, in the group dosed with 1% PPG 750, there was a slight increase in liver and kidney weights; there were no histological changes. Neither of the doses resulted in a central nervous system stimulatory effect.

Genotoxicity

No data are available.

Carcinogenicity

No data are available.

Reproductive/Developmental Toxicity

No data are available.

Key Study/Critical Effect for Screening Criteria

Several rat subchronic toxicity studies indicate a NOAEL of 1% PPG in diet (500 mg/kg/day). In one study, it was reported that there was a slight increase in liver and kidney weights (no data are provided to determine if the change in organ weights were statistically significant). Nevertheless, these organ weight changes may not be considered adverse since there were no accompanying histopathologic changes.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 500/1,000 = 0.5 mg/kg/day

Drinking water guidance value = 1.75 ppm

Andersen F.A. (1994) Final report on the safety assessment of propylene glycol and polypropylene glycols. Int. J. Toxicol. 13: 437- 491.

Benzenesulfonic acid, 4-ethyenyl-, sodium salt, homopolymer
(CAS No. 25704-18-1)

Acetic acid ethenyl ester, polymer with ethanol
(CAS No. 25213-24-5)

Vinylidene chloride/methacrylate copolymer
(CAS No. 25038-72-6)

Polyvinyl acetate, partially hydrolyzed
(CAS No. 30443-60-5) THIS IS NOT THE CORRECT CASRN

All of the these substances are polymers.

Mammalian toxicity data was located for only for acetic acid, ethenyl ester, polymer with ethanol (CAS No. 25213-24-5) on a supplier's MSDS. However, all of the polymers listed above are expected to exhibit similar toxicity profiles.

As polymers, they are not expected to be absorbed by the oral, dermal or inhalation routes of exposure due to their large molecular weights. They are also expected to be stable in biological media and resistant to metabolism.

This polymers are expected to be essentially acutely non-toxic by the oral, dermal and inhalation routes of exposure. The oral LD_{50} in rats for CAS No. 25213-24-5 was reported to be >11,000 mg/kg. Under certain conditions, dusts may be formed, which is to be considered as a nuisance dust. The polymers are expected to be non-irritating and not dermal sensitizers. No irritation or sensitization was observed in guinea pigs from CAS No. 25213-24-5.

These polymers are not expected to exhibit any systemic toxicity.

DuPont (2006). MSDS for "ELVANOL" 60-30, revised 27-Oct-2006.

Toxicity Profile

Sodium carbonate
(CAS No. 497-19-8)

Sodium carbonate has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Sodium carbonate is a strong alkaline compound with a pH of 11.6 for a 0.1M aqueous solution. The pKa of carbonate (CO_3^{2-}) is 10.33, which means that at a pH of 10.33 both carbonate and bicarbonate are present in equal amounts.

In water, sodium carbonate dissociates into sodium ion (Na^+) and carbonate (CO_3^{2-}). The carbonate ions will react with water, resulting in the formation of bicarbonate and hydroxide, until an equilibrium is established.

Sodium carbonate is used in many countries (*e.g.* U.S. and EU) as a food additive. It is regarded as a 'Generally Recognised as Safe' (GRAS) substance in food with no limitation other than current good manufacturing practice.

Acute Toxicity

An acute oral LD_{50} of sodium carbonate monohydrate in rats is 2,800 mg/kg, and the acute dermal LD_{50} is >2,000 mg/kg. These studies were done with sodium carbonate monohydrate but due to the relatively low water content of sodium carbonate monohydrate, the toxicity of sodium carbonate is not expected to be significantly different. The LC_{50}s for guinea pigs, mice and rats were 800, 1,200 and 2,300 mg/m , respectively, when male animals were exposed for 2 hours to sodium combustion products containing mainly sodium carbonate.

Irritation

Skin irritation studies have been performed with solid sodium carbonate and a 50 % solution of sodium carbonate with both animals and human volunteers. Erythema and edema were not observed for the intact skin. Thus, sodium carbonate has little to no skin irritation potential.

The available eye irritation tests show differing results. Studies using a dose of 0.1 ml sodium carbonate monohydrate and sodium carbonate (anhydrous) resulted in a classification of irritating and highly irritating, respectively. However, based on a study with a dose of 0.1 g sodium carbonate it was not classified as an ocular irritant. Overall, the results indicat that sodium carbonate is irritating to the eyes.

Sensitization

No data are available.

Repeated Dose Toxicity

No animal data are available on repeated dose toxicity studies by the oral route. Carbonate would be neutralized in the stomach by the low pH of the gastric juice and would not be available for uptake into the body.

Genotoxicity

The available *in vitro* mutagenicity test with sodium carbonate was negative.

Carcinogenicity

No data are available.

Reproductive/Developmental Toxicity

Aqueous solutions of sodium carbonate were administered daily via oral intubation to pregnant mice at doses ranging from 3.4 to 340 mg/kg during days 6-15 of gestation. There was no effect on implantation or on the survival of dams and fetuses. There were no significant differences in soft and skeletal tissue anomalies between treated and control animals. Negative results were reported for rats and rabbits for daily doses from 2.45 to 245 mg/kg and 1.79 to 179 mg/kg, respectively.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water screening value for sodium (180 ppm, aethestic) and pH may apply to sodium carbonate.

References

OECD (2002a). IUCLID Data Set for Sodium carbonate (CAS No. 497-19-8), UNEP Publications.

OECD (2002b). Screening Information Dataset (SIDS) Initial Assessment Report for Sodium carbonate (CAS No. 497-19-8), UNEP Publications.

Toxicity Profile

Sodium hydroxide
(CAS No. 1310-73-2)

Sodium hydroxide (NaOH) has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Sodium hydroxide (NaOH) is present in the environment as sodium (Na^+) and hydroxyl ions (OH^-). Sodium is a normal constituent of the blood and an excess is excreted in the urine. A significant amount of sodium is taken up via the food because the normal uptake of sodium via food is 3.1-6.0 g per day according to Fodor *et al.* (1999). Exposure to NaOH could potentially increase the pH of the blood. However, the pH of the blood is regulated between narrow ranges to maintain homeostasis (pH of 7.4 to 7.5) by urinary excretion of bicarbonate and via exhalation of carbon dioxide.

Acute Toxicity

An oral LD_{50} of a 1-10% solution of NaOH in rabbits was reported to be 325 mg/kg (expressed as 100% NaOH). Mortality was also observed when 1% NaOH was dosed, but in this case, the applied volume was relatively high (24 mL per kg body weight).

Irritation

A NaOH solution of 8% can be considered corrosive based on animal data. Human data indicate that concentrations of 0.5 to 4% were irritating. In two different studies a concentration of 0.5% was irritating for only 55 and 61% of the volunteers, respectively. Thus, it is assumed that a concentration, which is slightly lower than 0.5%, is the non-irritating concentration.

The available animal data on eye irritation showed that the non-irritant level was 0.2-1.0 %, while the corrosive concentration was 1.2 % or >2%.

Sensitization

Male volunteers were exposed on the back to sodium hydroxide concentrations of 0.063 – 1.0% (induction). After 7 days the volunteers were challenged to a concentration of 0.125%. The irritant response correlated well with the concentration of NaOH, but an increased response was not observed when the previously patch tested sites were re-challenged. Based on this study sodium hydroxide has no skin sensitization potential.

Repeated Dose Toxicity

No animal data are available on repeated dose toxicity studies by oral, dermal, inhalation or by other routes for NaOH. It is not useful to study the repeated dose toxicity of hydroxide via an oral study because at high concentrations the substance is corrosive or irritating, while at low concentrations the hydroxide will be neutralized in the stomach by gastric juice, which has a very low pH.

Genotoxicity

Both the *in vitro* and the *in vivo* genotoxicity tests are negative.

Carcinogenicity

No carcinogenicity studies on sodium hydroxide were identified.

Reproductive Toxicity

No valid studies were identified regarding toxicity to reproduction in animals after oral, dermal or inhalation exposure to NaOH. It is not useful to study the reproduction/developmental toxicity of hydroxide via an oral study because at high concentrations the substance is corrosive or irritating, while at low concentrations the hydroxide will be neutralized in the stomach by gastric juice, which has a very low pH.

Developmental Toxicity

No valid studies were identified regarding developmental toxicity in animals after oral, dermal or inhalation exposure to NaOH. It is not useful to study the reproduction/developmental toxicity of hydroxide via an oral study because at high concentrations the substance is corrosive or irritating, while at low concentrations the hydroxide will be neutralized in the stomach by gastric juice, which has a very low pH.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for pH may apply to sodium hydroxide.

Toxicity Profile

Talc
(CAS No. 61789-40-0)

Talc refers to both mineral talc and industrial mineral products that are marketed under the name talc and contain proportions of mineral talc that range from about 35% to almost 100%. Industrial talc generally refers to products that contain abundant minerals other than talc; cosmetic talc now normally contains >98% talc but the content may have been lower in the past. Pharmaceutical talc contains >99% talc. Talcum powder is cosmetic-grade talc.

Talc is a mineral composed of hydrated magnesium silicate with the chemical formula $Mg_3Si4O_{10}(OH)_2$ or $H_2Mg_3(SiO_3)_4$. Talc is not soluble in water.

The U.S. Food and Drug Administration (FDA) regulates talc and states that it is generally recognized as safe for use in color additives in foods, drugs and cosmetics, and in paper, paper products, cotton and cotton fabrics that come into contact with food. The Food Chemical Codex (2003) provides specifications for food-grade talc, including the statement that "talc derived from deposits that are known to contain associated asbestos is not food grade." Under the voluntary guidelines initiated in 1976, the Cosmetic, Toiletry, and Fragrances Association stated that all cosmetic talc should contain at least 90% platy talc (hydrated magnesium silicate) that is free from detectable amounts (<0.5%) of fibrous, asbestos minerals.

Toxicokinetics (Oral)

The absorption and disposition of ^{3}H-labeled talc in rats, mice, and guinea pigs administered a single oral dose was studied by Phillips *et al.* (1978). The oral doses were 50 mg/kg for rats, 40 mg/kg for mice, and 25 mg/kg for guinea pigs. In rats, mice, and guinea pigs, more than 95% of the dose was excreted in the feces 3 to 4 days after dosing. Less than 2% of the radioactivity was recovered in the urine. This radioactivity probably reflected contamination of urine samples with feces. No radioactivity was found in the liver or kidneys of these animals. This information suggests that talc is not absorbed from the gastrointestinal tract following oral exposure.

Acute Toxicity

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Male and female Wistar rats were given in their diet 0 or 50 mg/kg of commercial talc [characteristics unspecified] for the life of the animals (average survival was 702 and 649 days, respectively). There was no significant difference in the talc-fed animals compared with control animals (Gibel *et al.*, 1976).

Male and female Wistar-derived rats were given in their diet 100 mg Italian talc (grade 00000; ready milled; mean particle size, 25 μm; containing 92% talc, 3% chlorite, 1% carbonate minerals and 0.5–1% quartz) per rat per day for 5 months (talc-containing diet was actually given for 101 days) and were then maintained on basal diet for life (average survival, 614 days). No differences in tumor incidence were noted between treated animals and control animals (eight/sex for an average survival of 641 days) (Wagner *et al.*, 1977).

In humans and experimental animals, the effects of talc are dependent on the route of exposure, and the dose and properties of the talc. Talc pneumoconiosis was somewhat more prevalent and severe among miners exposed to talc containing asbestiform minerals and/or asbestos than among those exposed to talc without such contaminants. However, the role of quartz and asbestos in the observed pneumoconiosis could not be ruled out. Among drug users, intravenous injection of talc present as a filler in the drugs resulted in microembolization in a variety of organs and alterations in pulmonary function. In animal studies, talc has been shown to cause granulomas and mild inflammation when inhaled. Observations of the effects that occurred in the lungs of rats exposed by inhalation to talc suggested that the operative mechanisms may be similar to those identified for carbon black, and talc is known to cause the release of cytokines, chemokines and growth factors from pleural mesothelial cells.

IARC: There is *inadequate evidence* in humans for the carcinogenicity of inhaled talc not containing asbestos or asbestiform fibres. There is *limited evidence* in experimental animals for the carcinogenicity of talc not containing asbestos or asbestiform fibres. Inhaled talc not containing asbestos or asbestiform fibres is *not classifiable as to its carcinogenicity (Group 3).*

Genotoxicity

The IARC (1987) review of talc included unpublished results from a 1974 study conducted by Litton Bionetics that showed no mutagenic activity for talc *in vitro* or *in vivo.* Talc did not induce mutations in *Salmonella typhimurium* strains TA1530 or HisG46, or in the yeast, *Saccharomyces cerevisiae.* No chromosomal aberrations were observed in human fibroblasts treated with talc *in vitro. In vivo* tests conducted in rats gave negative results for induction of chromosomal aberrations in bone marrow cells and dominant lethal mutations in germinal cells.

Three samples of respirable talc failed to elicit significant unscheduled DNA synthesis (10, 20 and 50 μg/cm^2, 24 hours), sister chromatid exchange or aneuploidy (2, 5, 10 and 15 μg/cm^2, 48 hours) in rat pleural mesothelial cells, in contrast to various positive controls. The three samples, *i.e.* Spanish talc (No. 5725), Italian talc (No. 5726) and French talc (No. 7841), contained 90–95% talc; the remaining contents were chlorite and dolomite. Electron microscopy analysis revealed that talc particles were taken up by the rat pleural mesothelial cells, but no aneuploidy was observed in metaphases (Endo-Capron *et al.*, 1993).

Reproductive Toxicity

No data are available.

Developmental Toxicity

No teratologic effects were observed in hamsters, rats, mice, or rabbits after oral administration of talc. The doses used were 1,600 mg/kg for rats and mice on days *6* through 15 of gestation; 1,200 mg/kg for hamsters on day 6 through 10 of gestation; and 900 mg/kg for rabbits on days 6 through 18 of gestation.

Key Study/Critical Effect for Screening Criteria

There are no adequate studies for which to derive a oral reference dose. Talc is poorly absorbed from the gastrointestinal tract, if at all, and the limited data available by the oral route indicate that talc is essentially non-toxic by the oral route of exposure.

Toxicity Profile

Tetramethylammonium chloride
(CAS No. 75-57-0)

Surrogates:
Didecyldimethylammonium chloride
(CAS No. 7173-51-5)
Dodecyltrimethylammonium chloride
(CAS No. 112-00-5)

No data could be located on tetramethylammonium chloride. Toxicity data are available for didecyldimethylammonium chloride (DDAC) and dodecyltrimethyl-ammonium chloride (DTAC). Thus, these two substances have been used as surrogates for the alkylated quaternary chloride.

Acute Toxicity

The oral LD_{50} of 100% DDAC has been reported to be 84 mg/kg in rats and 268 mg/kg in mice. The oral LD_{50} of a 5-25% solution of DDAC in rats was reported to be 1,190 mg/kg (595 to 297 mg a.i./kg). The acute dermal LD_{50} of a 80% solution of DDAC in rats is 3,342 mg/kg (2674 mg a.i./kg).

The acute oral LD_{50} of DTAC (24.7% aq. soln.) in rats is 490 mg/kg. The acute oral LD_{50} of DTAC (37.35% aq. soln.) in rats is 560 mg/kg.

Irritation

DDAC is a severe skin and eye irritant to rabbits.

Sensitization

DDAC is not a dermal sensitizer to guinea pigs or to humans.

Repeatd Dose Toxicity

Mice were given in their diet 0, 100, 300, 600, 1,000 or 3,000 ppm DDAC for 89-90 days. For the lowest four dose groups, these doses correspond to mean intake levels of approximately 18, 52, 107, and 182 mg/kg for males, and 23, 68, 134, and 224 mg/kg for females. High mortality in the 3,000 ppm groups prohibited calculation of daily intakes. Treatment of mice with 3,000 ppm DDAC in the diet for several days resulted in virtually

100% mortality in both sexes, with only one male surviving to termination of the study. Death was attributed to treatment-related severe wasting and dehydration resulting from gastrointestinal effects. Treatment with 1,000 ppm DDAC produced a 5% decrease in body weight in males with associated decreases in body weight gain. Similar depressed body weight in females from this group was assumed to be related to DDAC exposure. No other changes were observed in males or females in the other dose groups. The NOEL for this study is 600 ppm (107 and 134 mg/kg/day for males and females, respectively).

Rats were given in their diet 0, 100, 300, 600, 1,000 or 3,000 ppm DDAC for 89-90 days. For the lowest four dose groups, these doses correspond to mean intake levels of approximately 6, 18, 37, and 61 mg/kg for males, and 8, 22, 44, and 74 mg/kg for females. High mortality in the 3,000 ppm group prohibited calculation of mean daily intakes. Dietary exposure to 3,000 ppm DDAC resulted in 80% mortality in both sexes. The three rats of each sex of this group that survived to the end of the study exhibited markedly reduced body weights, fluid- or gas-filled intestines at necropsy, and inflammation of the beginning of the large intestines (typhlitis). Pathological changes in clinical chemistry included decreased serum glucose and protein concentrations in both sexes, decreased albumin and globulin concentrations in females, and increased erythrocyte count and hemoglobin and hematocrit concentrations in males. Administration of 1,000 ppm of less of DDAC resulted in no treatment-related effects. The NOEL for this study is 61 and 74 mg/kg/day for males and females, respectively.

Male and female beagle dogs were given DDAC in their diet at doses of 0, 5, 15 and 50 mg/kg for 90 days. There was marked decrease in body weight gain, food consumption and food efficiency in the 50 mg/kg dose group. Clinical chemistry, hematology, urinalysis, and pathological results did not reveal any treatment-related effects. The NOAEL for this study is 15 mg/kg/day.

Beagle dogs were dosed orally with 0, 3, 10, or 30 mg/kg DDAC for 52 weeks. During the first four and a half weeks of the study, several dogs in the 30 mg/kg group showed potentially life threatening decreases in body weight and food consumption. The dose was therefore decreased to 20 mg/kg/day. In some cases, depressions in weight and food consumption were so severe that the dogs in this group were removed from treatment completely during study days 31-36, and then reinstated at the 20 mg/kg/day. Administration of 3 or 20 mg/kg/day was not associated with mortality, changes in organ weights, gross pathological findings, ophthalmologic changes, or microscopic changes in selected organs and tissues. The 20 mg/kg/day dose was associated with decreases in mean erythrocyte counts; hemoglobin and hematocrit values; and mean total cholesterol, total protein, and albumin values. The 10 and 20 mg/kg/day doses were associated with an increased incidence of emesis, salivation, and soft/mucoid/liquid feces compared to controls. The NOEL for systemic toxicity was considered to be 10 mg/kg/day.

Sprague-Dawley rats were given in their diet 0, 300, 750, or 1,500 ppm DDAC for at least 104 weeks. These doses corresponded to approximate DDAC intakes of 13, 32, and 64 mg/kg/day for males, and 16, 41, and 83 mg/kg/day for females. Treatment-related

decreases in body weight and food consumption in both males and females were observed in the 1,500 ppm group. In addition, possible treatment-related microscopic changes including hyperplasia of bile ducts in female rats and changes in mesenteric lymph nodes in male and female rats related to blood in the sinuses were observed in the 1,500 ppm group. No treatment-related effects were seen in the type of incidence of clinical signs, survival, palpable masses, clinical pathology, organ weights, gross anatomic pathology, or ophthalmology. The NOEL for toxicity was considered to be 750 ppm (32 and 41 mg/kg/day for males and females, respectively).

CD-1 mice were administered in their diet 0, 100, 500, or 1,000 ppm DDAC for at least 78 weeks. The approximate mean intake levels were 15, 76.3, and 155.5 mg/kg/day for males and 18.6, 93.1, and 193.1 mg/kg/day for females. Treatment-related findings included decreased body weights and body weight gains in both male and females from the 1,000 ppm groups. There were no treatment-related clinical signs of toxicity, increases in palpable masses, changes in food consumption, differences in organ weights or observations at necropsy or differences in histopathological findings. The NOEL for this study was considered to be 500 ppm (76.3 and 93.1 mg/kg/day for males and females, respectively).

Genotoxicity

Several studies evaluating the mutagenicity of DDAC have all given negative results. DDAC was not mutagenic to several strains of *S. typhimurium* in a bacterial reverse mutation assay with or without metabolic activation. DDAC was tested in the CHO/HGPRT forward mutation assay and was not mutagenic in the presence or absence of metabolic activation. DDAC did not induce chromosomal aberrations in CHO cells with or without metabolic activation. In the *in vitro* rat primary hepatocyte unscheduled DNA synthesis (UDS) assay, DDAC did not induce significant increases in UDS. No chromosomal damage was observed in the bone marrow of rats in an *in vivo* cyogenetics assay.

DTAC (24.7% aq. soln.) was not mutagenic to bacteria in a reverse mutation assay with or without metabolic activation. DTAC (24.7% aq. soln.) was not mutagenic in a mouse lymphoma assay with or without metabolic activation. DTAC was inactive in a rat primary hepatocyte UDS assay. DTAC was not genotoxic when given by oral gavage in a rat bone marrow micronucleus assay.

Carcinogenicity

Sprague-Dawley rats received DDAC in their diet at concentrations of 0, 300, 750 or 1,500 ppm for at least 104 weeks. These doses corresponded to approximate mean DDAC intakes of 13, 32, and 64 mg/kg/day for males, and 16, 41, and 83 mg/kg/day for females. DDAC was not considered to be carcinogenic under the conditions of this study.

CD-1 mice were administered in the diet 0, 100, 500, or 1,000 ppm DDAC for at least 78 weeks. The approximate mean intake levels were 15, 76.3, and 155.5 mg/kg/day for males, and 18.6, 93.1, and 193.1 mg/kg/day for females. DDAC was not considered to be carcinogenic under the conditions of this study.

Reproductive Toxicity

A two-generation reproductive toxicity study has been conducted with DDAC. Sprague-Dawley rats were given in their diet 0, 300, 750 or 1,500 ppm for two generations. Results indicate that continuous exposure to DDAC in the diet for two generations resulted in no adverse reproductive effects. Parental toxicity was observed at 1,500 ppm (~112.6 mg/kg/day), limited to body weight reduction, weight gain depression, and decreased food consumption. Postnatal toxicity at 1,500 ppm was indicated by reduced pup body weights. Based on decreased body weight/weight gain and food consumption, the parental Toxicity NOAEL = 750 ppm (56 mg/kg/day); LOAEL = 1500 ppm (113 mg/kg/day). Based on decreased pup body weight/weight gain, the reproductive toxicity NOAEL = 750 ppm (56 mg/kg/day); LOAEL = 1500 ppm (113 mg/kg/day).

Developmental Toxicity

Female NZ rabbits were given by oral gavage 0, 1.0, 3.0 or 10 mg/kg/day of DDAC during GD 6-18. Four of the 16 does in the highest group died prior to GD 13. One doe at 10 mg/kg and 2 does at 1.0 mg/kg delivered early and were removed from the study. Nonlethal indications of maternal toxicity were evident at 3 and 10 mg/kg, as evidenced by reduced weight gain and clinical signs during the treatment period. Developmental toxicity, including increased incidences of fetal mortality and reduced fetal body weight per litter, were observed only at the highest dose. No teratogenicity was observed at any dose level. The NOEL for maternal toxicity is 1 mg/kg/day, and the NOEL for developmental toxicity is 3 mg/kg/day.

Female Sprague-Dawley rats were given by oral gavage 0, 1, 10 or 20 mg/kg DDAC during GD 6-15. No females died, aborted, delivered early, or were removed early from the study. Maternal toxicity was indicated at 10 and 20 mg/kg by characteristic clinical signs of audible respiration. Reductions in body weight and food consumption were also observed at 20 mg/kg during the treatment period. No evidence of developmental toxicity including teratogenicity was observed at any dose level. The NOEL for maternal toxicity was 1 mg/kg/day. The NOEL for developmental toxicity is >20 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The lowest NOAEL was 10 mg/kg/day for dogs in the one-year chronic toxicity study. The LOAEL of 20 mg/kg/day was based on increased incidence of clinical signs in males and females, and decreased total cholesterol levels in females.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral Reference Dose = 20/100 = 0.2 mg/kg/day

Drinking water guidance value = 0.7 ppm

APPENDIX F.2 HALLIBURTON WATER AND GUAR BASED SYSTEMS

Toxicity Profile

Acetic acid
(CAS No. 64-19-7)

Acetic acid dissociates in aqueous media to H^+ and the acetate anion ($CH_3CO_2^-$). It is naturally occurring as the acid in apple cider vinegar and other fruit-derived products. It and several of its salts are commonly used as food additives (*e.g.*, as flavor enhancers) and are listed as Generally Recognized as Safe (GRAS) by the U.S. Food and Drug Administration (FDA).

pH: 2.5 at 50 g/L and 20°C
pK_a: 4.76 @ 20°C

Acute Toxicity

The oral LD_{50} in rats is 4,950 mg/kg, and the dermal LD_{50} in rabbits is 1,060 mg/kg. The 4-hour LC_{50} in rats is 11.4 mg/L.

Irritation

In the EU, acetic acid is classified as a skin and eye irritant at concentrations <25%. At ≥25%, it is classified as corrosive to the skin.

Sensitization

No data are available.

Repeated Dose Toxicity

In an 8-month study, rats dosed with 60 mg/kg acetic acid (three times per week) developed hyperplasia in the esophagus and forestomach.

Genotoxicity

Acetic acid was not mutagenic to *Salmonella typhimurium* strains TA 98, TA 100, TA 1535, TA 1537, and TA 1538 in an *in vitro* bacterial mutation assay with or without metabolic activation. Acetic acid (in media adjusted to a pH of 8.5) was also not genotoxic in an *in vitro* chromosomal aberration test using Chinese Hamster Ovary cells with or without metabolic activation.

Carcinogenicity

No adequate carcinogenicity studies have been conducted on acetic acid.

Reproductive Toxicity

No studies could be located.

Developmental Toxicity

There were no effects on implantations or on maternal or fetal survival in mice, rats, or rabbits at doses up to 1,600 mg/kg.

Key Study/Critical Effect for Screening Criteria

There are no repeat dose toxicity studies that were considered adequate for human health risk assessment. The only study reported on the toxicity of acetic acid by oral gavage showed effects of irritation (probably due to the pH of acetic acid) at the site of contact in the gastrointestinal tract. No systemic effects were reported.

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) has maintained a group ADI of "not limited" for acetic acid and its potassium and sodium salts.

The Australian drinking water guidance value for pH may apply to acetic acid.

Toxicity Profile

Alkylated Quaternary chloride

Surrogates:
Didecyldimethylammonium chloride
(CAS No. 7173-51-5)
Dodecyltrimethylammonium chloride
(CAS No. 112-00-5)

No data could be located on this alkylated quaternary chloride. Toxicity data are available for didecyldimethylammonium chloride (DDAC) and dodecyltrimethyl-ammonium chloride (DTAC). Thus, these two substances have been used as surrogates for the alkylated quaternary chloride.

Acute Toxicity

The oral LD_{50} of 100% DDAC has been reported to be 84 mg/kg in rats and 268 mg/kg in mice. The oral LD_{50} of a 5-25% solution of DDAC in rats was reported to be 1,190 mg/kg (595 to 297 mg a.i./kg). The acute dermal LD_{50} of a 80% solution of DDAC in rats is 3,342 mg/kg (2674 mg a.i./kg).

The acute oral LD_{50} of DTAC (24.7% aq. soln.) in rats is 490 mg/kg. The acute oral LD_{50} of DTAC (37.35% aq. soln.) in rats is 560 mg/kg.

Irritation

DDAC is a severe skin and eye irritant to rabbits.

Sensitization

DDAC is not a dermal sensitizer to guinea pigs or to humans.

Repeatd Dose Toxicity

Mice were given in their diet 0, 100, 300, 600, 1,000 or 3,000 ppm DDAC for 89-90 days. For the lowest four dose groups, these doses correspond to mean intake levels of approximately 18, 52, 107, and 182 mg/kg for males, and 23, 68, 134, and 224 mg/kg for females. High mortality in the 3,000 ppm groups prohibited calculation of daily intakes. Treatment of mice with 3,000 ppm DDAC in the diet for several days resulted in virtually 100% mortality in both sexes, with only one male surviving to termination of the study. Death was attributed to treatment-related severe wasting and dehydration resulting from

gastrointestinal effects. Treatment with 1,000 ppm DDAC produced a 5% decrease in body weight in males with associated decreases in body weight gain. Similar depressed body weight in females from this group was assumed to be related to DDAC exposure. No other changes were observed in males or females in the other dose groups. The NOEL for this study is 600 ppm (107 and 134 mg/kg/day for males and females, respectively).

Rats were given in their diet 0, 100, 300, 600, 1,000 or 3,000 ppm DDAC for 89-90 days. For the lowest four dose groups, these doses correspond to mean intake levels of approximately 6, 18, 37, and 61 mg/kg for males, and 8, 22, 44, and 74 mg/kg for females. High mortality in the 3,000 ppm group prohibited calculation of mean daily intakes. Dietary exposure to 3,000 ppm DDAC resulted in 80% mortality in both sexes. The three rats of each sex of this group that survived to the end of the study exhibited markedly reduced body weights, fluid- or gas-filled intestines at necropsy, and inflammation of the beginning of the large intestines (typhlitis). Pathological changes in clinical chemistry included decreased serum glucose and protein concentrations in both sexes, decreased albumin and globulin concentrations in females, and increased erythrocyte count and hemoglobin and hematocrit concentrations in males. Administration of 1,000 ppm of less of DDAC resulted in no treatment-related effects. The NOEL for this study is 61 and 74 mg/kg/day for males and females, respectively.

Male and female beagle dogs were given DDAC in their diet at doses of 0, 5, 15 and 50 mg/kg for 90 days. There was marked decrease in body weight gain, food consumption and food efficiency in the 50 mg/kg dose group. Clinical chemistry, hematology, urinalysis, and pathological results did not reveal any treatment-related effects. The NOAEL for this study is 15 mg/kg/day.

Beagle dogs were dosed orally with 0, 3, 10, or 30 mg/kg DDAC for 52 weeks. During the first four and a half weeks of the study, several dogs in the 30 mg/kg group showed potentially life threatening decreases in body weight and food consumption. The dose was therefore decreased to 20 mg/kg/day. In some cases, depressions in weight and food consumption were so severe that the dogs in this group were removed from treatment completely during study days 31-36, and then reinstated at the 20 mg/kg/day. Administration of 3 or 20 mg/kg/day was not associated with mortality, changes in organ weights, gross pathological findings, ophthalmologic changes, or microscopic changes in selected organs and tissues. The 20 mg/kg/day dose was associated with decreases in mean erythrocyte counts; hemoglobin and hematocrit values; and mean total cholesterol, total protein, and albumin values. The 10 and 20 mg/kg/day doses were associated with an increased incidence of emesis, salivation, and soft/mucoid/liquid feces compared to controls. The NOEL for systemic toxicity was considered to be 10 mg/kg/day.

Sprague-Dawley rats were given in their diet 0, 300, 750, or 1,500 ppm DDAC for at least 104 weeks. These doses corresponded to approximate DDAC intakes of 13, 32, and 64 mg/kg/day for males, and 16, 41, and 83 mg/kg/day for females. Treatment-related decreases in body weight and food consumption in both males and females were observed in the 1,500 ppm group. In addition, possible treatment-related microscopic

changes including hyperplasia of bile ducts in female rats and changes in mesenteric lymph nodes in male and female rats related to blood in the sinuses were observed in the 1,500 ppm group. No treatment-related effects were seen in the type of incidence of clinical signs, survival, palpable masses, clinical pathology, organ weights, gross anatomic pathology, or ophthalmology. The NOEL for toxicity was considered to be 750 ppm (32 and 41 mg/kg/day for males and females, respectively).

CD-1 mice were administered in their diet 0, 100, 500, or 1,000 ppm DDAC for at least 78 weeks. The approximate mean intake levels were 15, 76.3, and 155.5 mg/kg/day for males and 18.6, 93.1, and 193.1 mg/kg/day for females. Treatment-related findings included decreased body weights and body weight gains in both male and females from the 1,000 ppm groups. There were no treatment-related clinical signs of toxicity, increases in palpable masses, changes in food consumption, differences in organ weights or observations at necropsy or differences in histopathological findings. The NOEL for this study was considered to be 500 ppm (76.3 and 93.1 mg/kg/day for males and females, respectively).

Genotoxicity

Several studies evaluating the mutagenicity of DDAC have all given negative results. DDAC was not mutagenic to several strains of *S. typhimurium* in a bacterial reverse mutation assay with or without metabolic activation. DDAC was tested in the CHO/HGPRT forward mutation assay and was not mutagenic in the presence or absence of metabolic activation. DDAC did not induce chromosomal aberrations in CHO cells with or without metabolic activation. In the *in vitro* rat primary hepatocyte unscheduled DNA synthesis (UDS) assay, DDAC did not induce significant increases in UDS. No chromosomal damage was observed in the bone marrow of rats in an *in vivo* cyogenetics assay.

DTAC (24.7% aq. soln.) was not mutagenic to bacteria in a reverse mutation assay with or without metabolic activation. DTAC (24.7% aq. soln.) was not mutagenic in a mouse lymphoma assay with or without metabolic activation. DTAC was inactive in a rat primary hepatocyte UDS assay. DTAC was not genotoxic when given by oral gavage in a rat bone marrow micronucleus assay.

Carcinogenicity

Sprague-Dawley rats received DDAC in their diet at concentrations of 0, 300, 750 or 1,500 ppm for at least 104 weeks. These doses corresponded to approximate mean DDAC intakes of 13, 32, and 64 mg/kg/day for males, and 16, 41, and 83 mg/kg/day for females. DDAC was not considered to be carcinogenic under the conditions of this study.

CD-1 mice were administered in the diet 0, 100, 500, or 1,000 ppm DDAC for at least 78 weeks. The approximate mean intake levels were 15, 76.3, and 155.5 mg/kg/day for males, and 18.6, 93.1, and 193.1 mg/kg/day for females. DDAC was not considered to be carcinogenic under the conditions of this study.

Reproductive Toxicity

A two-generation reproductive toxicity study has been conducted with DDAC. Sprague-Dawley rats were given in their diet 0, 300, 750 or 1,500 ppm for two generations. Results indicate that continuous exposure to DDAC in the diet for two generations resulted in no adverse reproductive effects. Parental toxicity was observed at 1,500 ppm (~112.6 mg/kg/day), limited to body weight reduction, weight gain depression, and decreased food consumption. Postnatal toxicity at 1,500 ppm was indicated by reduced pup body weights. Based on decreased body weight/weight gain and food consumption, the parental Toxicity NOAEL = 750 ppm (56 mg/kg/day); LOAEL = 1500 ppm (113 mg/kg/day). Based on decreased pup body weight/weight gain, the reproductive toxicity NOAEL = 750 ppm (56 mg/kg/day); LOAEL = 1500 ppm (113 mg/kg/day).

Developmental Toxicity

Female NZ rabbits were given by oral gavage 0, 1.0, 3.0 or 10 mg/kg/day of DDAC during GD 6-18. Four of the 16 does in the highest group died prior to GD 13. One doe at 10 mg/kg and 2 does at 1.0 mg/kg delivered early and were removed from the study. Nonlethal indications of maternal toxicity were evident at 3 and 10 mg/kg, as evidenced by reduced weight gain and clinical signs during the treatment period. Developmental toxicity, including increased incidences of fetal mortality and reduced fetal body weight per litter, were observed only at the highest dose. No teratogenicity was observed at any dose level. The NOEL for maternal toxicity is 1 mg/kg/day, and the NOEL for developmental toxicity is 3 mg/kg/day.

Female Sprague-Dawley rats were given by oral gavage 0, 1, 10 or 20 mg/kg DDAC during GD 6-15. No females died, aborted, delivered early, or were removed early from the study. Maternal toxicity was indicated at 10 and 20 mg/kg by characteristic clinical signs of audible respiration. Reductions in body weight and food consumption were also observed at 20 mg/kg during the treatment period. No evidence of developmental toxicity including teratogenicity was observed at any dose level. The NOEL for maternal toxicity was 1 mg/kg/day. The NOEL for developmental toxicity was >20 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The lowest NOAEL was 10 mg/kg/day for dogs in the one-year chronic toxicity study. The LOAEL of 20 mg/kg/day was based on increased incidence of clinical signs in males and females, and decreased total cholesterol levels in females.

Toxicity Profile

Amorphous/Non-crystalline Silica
(CAS No. 7631-86-9[1])

Silica Gel
(CAS No. 112926-00-8)

Amorphous silica and silica gel have been reviewed in the OECD-SIDS program (OECD, 2004a,b).

The CAS No. 7631-86-9 is the general CAS No. for silicon dioxide which includes all forms of silicas (*e.g.* also crystalline and natural forms). Only the silica sub-classes, the synthetic amorphous silicas, are the subject of this assessment.

Synthetic amorphous silicas (SAS) are in powder form which have a low water solubility: ≤70 mg/L

Toxicokinetics

After oral ingestion, there is no accumulation of SAS in body tissues. Upon cessation of exposure, rapid elimination occurs. Intestinal resorption appears to be insignificant in animals and humans. In a human study, the small apparent increases in the urine output of human volunteers were remarkably low as compared with the high dose of 2,500 mg SiO_2 applied.

After daily oral administration of 1,500 mg/kg SAS (FK 700) as aqueous suspension to rats for one month, there was no accumulation of SiO_2 in the body: the average SiO_2 content was: 1.5 µg in the liver, 6.4 µg in the kidney, and 5.3 µg in the spleen. The corresponding control values were 1.8, 7.2 and 7.8 µg SiO_2, respectively.

In a similar experiment in rats receiving 20 daily oral doses of 100 mg SAS (HDK V15) per animal (about 500 mg/kg) each, tissue values were slightly increased in liver and kidney: in liver 4.2 µg (control value 1.8 µg), in the spleen 5.5 µg (7.2 µg) and in the kidneys 14.2 µg (7.8 µg).

In 12 human volunteers, no significant increased renal excretion of SiO_2 was found following single oral ingestion of 2,500 mg (AEROSIL 175 and FK 700).

Acute Toxicity

The acute oral administration of various forms of SAS (aqueous suspension or gel) failed to produce signs of toxicity or deaths in treated animals with LD_{50} values greater than the

top doses applied, either by gavage: >3100 to >20000 mg/kg in mice and rats; or in the diet for 24 hours.

Irritation

Synthetic amorphous silicas are not irritating to the skin of rabbits exposed to 0.19 g (one case) or 0.5 g of dry or moistened test item under occlusive conditions for 4 or 24 hours. All products tested as a powder (0.1 g) have shown no or only weak and transient irritating effects on the conjunctivae of the eyes of rabbits with the iris and cornea not affected at all.

Sensitization

No experimental data are available on the synthetic amorphous silicas. Medical surveillance records on workers gave no evidence of skin sensitization over decades of practical experience.

Repeated Dose Toxicity/Carcinogenicity

Fischer rats and B6C3F_1 mice were administered SAS in the diet at levels of 0, 1.25, 2.5, and 5% for 102 weeks. The animals were in good condition throughout and showed high survival. The tumor responses in all organs of SAS-fed rats and mice were not statistically significantly different from the controls. The NOAEL for rats and mice were 2,500 and 6,500 mg/kg/day, respectively.

Genotoxicity

There is no evidence for synthetic amorphous silica to induce mutations either *in vitro* or *in vivo* using standard genotoxicity tests.

Reproductive Toxicity

An early limited one-generation study on rats gave no evidence of adverse effects on reproduction performan*ce* at 500 mg/kg/day, the highest dose tested (NOAEL). But the reliability is poor due to the small group size of animals.

Developmental Toxicity

SAS was examined for embryotoxic and developmental effects during the gestation phase in various animals species, rat, mouse, rabbit and hamster, at oral doses up to 1,600 mg/kg/day. . There were no significant signs of maternal or embryotoxic/developmental toxic effects in any species tested. The number of abnormalities seen in either soft or skeletal tissues of the test groups did not differ from the frequencies occurring spontaneously in the control animals.

Key Study/Critical Effect for Screening Criteria

The lowest NOAEL from the two-year dietary study was 2,500 mg/kg/day for rats.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 2,500/100 = 2.5 mg/kg/day

Drinking water guidance value = 0.09 ppm

Toxicity Profile

1,2-Benzothiazolin-3-one
(CAS No. 2634-33-5)

Acute Toxicity

The rat oral LD_{50} is 670 mg/kg in males and 784 mg/kg in females. The rabbit dermal LD_{50} is >2,000 mg/kg.

Irritation

1,3-Benzothiazolin-2-one is a mild skin irritant and severe eye irritant to rabbits.

Sensitization

1,3-Benzeothiazolin-3-one is a skin sensitizer to guinea pigs.

Repeated Dose Toxicity

Decreased body weight, increased incidence of forestomach hyperplasia, and non-glandular stomach lesions were observed in rats in a rat subchronic oral toxicity study. The NOAEL is 8.42 mg/kg/day.

A dog subchronic oral toxicity study showed effects occurring at lower doses than in rats, and included alterations in blood chemistry (decreased plasma albumin, total protein, and alanine aminotransferase) and increased absolute liver weight. The NOAEL is 5 mg/kg/day.

Genotoxicity

All acceptable mutagenicity studies showed a negative mutagenic response for this chemical.

Carcinogenicity

No carcinogenicity studies are available.

Reproductive Toxicity

In a two-generation reproductive toxicity study, parental toxicity was observed at 500 ppm and was characterized by lesions in the stomach. In pups, toxic effects were reported at 1,000 ppm and consisted of preputial separation in males and impaired growth and survival in both sexes. There was no evidence of increased susceptibility of the offspring.

Developmental Toxicity

Developmental toxicity studies were conducted in rats with maternal effects including decreased body weight gain, decreased food consumption, and clinical toxicity signs (audible breathing, haircoat staining of the anogenital region, dry brown material around the nasal area) as well as increased mortality. Developmental effects consisted of increases in skeletal abnormalities (extra sites of ossification of skull bones, unossified sternebra), but no external or visceral abnormalities.

Key Study/Critical Effect for Screening Criteria

The U.S. EPA Office of Prevention, Pesticides and Toxic Substances (OPPTS) chronic oral reference dose is based on increased incidence of emesis and clinical chemistry alterations at 20 mg/kg/day in a subchronic toxicity study in dogs, with a NOAEL of 5 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 5/100 = 0.05 mg/kg/day

Drinking water guidance value = 0.2 ppm

Reference

U.S. Environmental Protection Agency, Reregistration Eligibility Decision for 1,2-Benzoisothiazolin-3-one (BIT), Office of Prevention, Pesticides and Toxic Substances, 739-R-05-007, September 2005.

Toxicity Profile

C10-C12 Alcohol Ethoxylates
(CAS No. 67254-71-1)

Alcohol ethoxylates (AE) are a class of non-ionic surfactants that have the basic structure $C_{x-y}AE_n$. The subscript (x-y) following the 'C' indicates the range of carbon chain units. AEs with carbon unit range between C8 to C18 are most commonly used in household detergent products. The hydrocarbon chain can be either linear or branched. AEs also contain an ethylene oxide (E) chain attached to the alcohol. The degree of ethylene oxide polymerization is indicated by the subscript (n) which indicates the average number of ethylene oxide units. In household products the average ethylene oxide chain length commonly ranges between 3 and 12 units.

The toxicity profile of C10-C12 alcohol ethoxylates has been developed from a risk assessment report on alcohol ethoxylates ranging from C8 to C18 prepared by the household cleaning product and chemical industry (HERA, 2009).

Acute Toxicity

The acute oral LD_{50} of C9-11AE2.5 in rats was calculated to be >4,000 mg/kg and <10,000 mg/kg. The acute oral LD_{50} of C7-9AE6 in rats was determined to be <2,000 mg/kg. The acute oral LD_{50} of C9-11AE8 in fasted rats was found to be 1,200 mg/kg. The oral LD_{50} in rats for C12-13AE6.5 is 2,100 mg/kg. The oral LD_{50} in rats for C12-15AE7 is 1,700 mg/kg. For C14-15AE11, the acute oral LD_{50} values were reported to be 720 mg/kg (neat) and 1,800 mg/kg (given as 50% (m/v) solution in corn oil). The oral LD_{50} in rats for C12-15AE11 is >2,00 mg/kg for males and between 1,000 and 2,000 mg/kg for females. The oral LD_{50} in rats for C14-15AE13 is 1,100 and 1,000 mg/kg in two separate studies.

The dermal LD_{50} of C7-9AE6 was >2 g/kg. The dermal LD_{50} values for AEs with an alkyl chain length of 9 – 11 carbon atoms in three different rat studies were determined to be >2,000 mg/kg and >4,000 mg/kg. An acute dermal LD_{50} value of >2,000 mg/kg was determined for C12-14AE3 and C12-14AE6 in two separate studies. The acute dermal LD_{50} of C12-15AE7 was determined to be >2,000 mg/kg.

The acute rat 4 hr-LC_{50} of C9-11AE5 generated as a mist was determined to be >0.22 mg/L. Talmage (1994) reported that alcohol ethoxylates were not acutely toxic to rats at concentrations less than or equal to their saturated vapor concentrations in air. Acute toxic thresholds were reached only when animals were exposed to the undiluted test chemical in the form of a respirable mist or aerosol. Under these conditions, 1- or 4-hour inhalation LC_{50} values ranged from 1.5 to 20.7 mg/L. Some studies reported no mortalities (1-hours LC_{50} -study) occurred at concentrations as high as 52 mg/L.

Irritation

Alcohol ethoxylates with varying alkyl chain lengths and ethoxylation degree were found to be slightly to severely irritating to skin in rabbits and rats. The degree of irritation was dependent on the type of patches used (open application versus full occlusion), the exposure time as well as the concentration of the test material. In humans, AEs are less irritating to skin than in animals. Neat applications of a range AEs in a 4-hr human patch test did not warrant these chemicals to be classified as skin irritants under EU legislation, while the same AEs would have been classified for skin irritation on the basis of animal data.

Alcohol ethoxylates range from mildly to severely irritating to rabbit eyes. Generally, concentration of 0.1% were non-irritating, and concentrations of 1 to 10% ranged from slight to moderately irritating. No relationship could be established between the chemical structures of the tested AEs and their eye irritation responses.

Sensitization

Alcohol ethoxylates should not be considered as skin sensitizers. A substantial amount of skin sensitization studies in guinea pigs following either the Magnusson-Kligman maximization or the Buehler testing protocol are available to evaluate the skin sensitization potential of AEs. Although a mild skin sensitization reaction was observed in a study following the Magnusson-Kligman protocol, the weight of evidence clearly supports the assessment that AEs should not be considered as skin sensitizers. This is further supported by clinical and market data that demonstrate the absence skin sensitization responses to AEs when tested under the conditions of the HRIPT or when used in AE containing consumer products.

Repeated Dose Toxicity

C10AE5 was fed to rats at doses of 0, 125, 250 or 500 mg/kg for 90 days. There were not treatment-related clinical signs, body weight gain, food consumption or feed efficiency. There was a slight increase in absolute liver weights as well as a trend toward a dose-dependent increase in the liver weight/body weight ratio, with a statistically significant increase in the high dose group. However, the histological evaluation did not reveal any indication of hepatotoxicity and therefore the increase in liver weights was not interpreted to be a toxicological effect. It can be considered to be an adaptive response as a result of extensive metabolism of the test compound by the liver. There were no other gross or histopathological changes that were considered treatment-related. The NOAEL for this study can be considered to be 500 mg/kg/day.

Rats were given in their diet 0, 125, 250, 500, 1,000 and 3,000 ppm C9-11AE6 for 90 days. There were no signs of toxicity at any dose level. The NOAEL is 3,000 ppm (approximately 150 mg/kg/day).

Rats were given in their diet 0. 04, 0.2 and 1.0% C9-11AE8 for 90 days. Lower body weight gain and decreased food consumption were noted in the 1% males and females and in the 0.2% females from week 1 through the end of the study. Further statistical analyses revealed a significant decrease in the mean body weight gain noted in the 1% females and the decreases in mean food consumption noted in the 1% males and females. The differences noted in the 0.2% females were not statistically significant. The investigators considered these observations to be the result of poor palatability of the test substance. There were no other treatment-related effects. The NOAEL for this study is 1.0% (about 400 mg/kg/day).

Rats were fed C12-15AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% and 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the 0.25% and higher dose groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the 0.25% groups and higher. There were not treatment-related changes in hematology, urinary and clinical chemistry parameters. The histological examination of the liver at necropsy revealed hepatocytic enlargement at 0.125% and higher, suggesting an increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (102 mg/kg/day).

Rats were fed C12-14AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% and 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the 0.25% and higher dose groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the 0.25% groups and higher. There were not treatment-related changes in hematology, urinary and clinical chemistry parameters. The histological examination of the liver at necropsy revealed hepatocellular hypertrophy at 0.125% and higher, suggesting an increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (110 mg/kg/day).

Wistar rats were fed C14-15AE7 in the diet at concentrations of 0, 300, 1,000, 3,000, and 10,000 ppm for 90 days. All animals survived until their scheduled necropsy date. Significant treatment-related effects on body weight (*i.e.*, reduced mean body weights in males at 10,000 ppm and in females at 3,000 ppm), food intake (*i.e.*, reduced intake in both sexes at 10,000 ppm and at 3,000 ppm for females), organ weights (*i.e.*, increased relative liver weight in both sexes at 3,000 and 10,000 ppm and in females also at 1,000 ppm; increased spleen weight in males at 10,000 ppm; clinical chemistry (*i.e.*, confined to 10,000 ppm dose groups; significantly higher urea, chloride and potassium levels in males; significantly higher urea, chloride and cholesterol levels in females) and hematology (*i.e.*, in both sexes at 10,000 ppm and in males also at 3,000 ppm increased

total leukocytes and lymphocytes; females at 10,000 ppm showed depression in numbers of neutrophils, mean cell volume and mean cell hemoglobin) were identified in one or both sexes fed with dietary concentrations of 3,000 and 10,000 ppm. There were no compound-related histopathological effects at any dose level. Minor, but statistically significant changes in liver weight, kidney weights and plasma urea concentration were recorded in female rats in the 1,000 ppm group were not of toxicological significance. The NOAEL for this study is 1,000 ppm (50 mg/kg/day).

Rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1%, 0.5% and 1% for 90 days. There were no treatment-related changes in body weight, food intake, and organ weights including those of the reproductive system, clinical chemistry and hematology at any treatment level. The NOAEL is 1% in the diet, which corresponded to 700 and 785 mg/kg/day for males and females, respectively.

Rats were fed C12-13AE6.5 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Rats were fed C14-15AE7 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Charles River rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1, 0.5 and 1% for two years. There was a dose-related decrease in body weights in the 0.5 and 1% females and in the 1% males, the likely cause being poor palatability of the diet. At study termination, elevated organ-to-body weight ratios were noted for the liver, kidney, heart and thyroid/parathyroid glands in the 1% dietary group. The only significant histopathological finding prevalent in all dose groups was a dose-related increase in incidence of focal myocarditis at 12 months but not at study termination at 2 years. No other treatment-related histopathology was noted. The NOAEL was established at the 0.5% dietary level, which corresponds to about 162 and 190 mg/kg/day for males and females, respectively.

Genotoxicity

In all available *in vitro* and *in vivo* genotoxicity assays, there was no indication of genetic toxicity of broad range of structurally different alcohol ethoxylates.

Carcinogenicity

Alcohol ethoxylates as a class are not carcinogenic by the oral route based of available oral long term toxicity/carcinogenicity studies on AEs.

Charles River rats were given in their diet 0, 0.1, 0.5 or 1% C14-15AE7 for two years. There was no treatment-related changes in general behavior and appearance. The survival rate of the test animals was comparable if not better than the controls. Body weights of 0.5% females and 1% males and females had significantly lower weight gains than the control. There were no treatment-related effects on organ weights and tumor incidence.

Sprague-Dawley rats were fed C14-15AE7 at 0.1, 0.5 and 1% in the diet for two years. A treatment-related body weight depression was observed in females at the two highest treatment levels and in males at the 1% dose level, probably due to the poor palatability of the diet. There was no evidence for any carcinogenic activity.

Sprague-Dawley rats were fed C12-13AE6.5 in the diet at doses up to 1% (500 mg/kg/day). Reduced food consumption was noted at the higher dose levels (*i.e.*, 0.5 and 1% for females and 1% for males), resulting in a lower body weight gain compared to the control group. No treatment-related histopathology was found and no increase in tumor incidence was observed.

Reproductive Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg/day). No treatment related effects in the parents or pups on general behaviour, appearance or survival were observed. Fertility of treated groups was comparable with the controls. The only observation was related to a reduced weight gain of parental rats and pups relative to the control at the 0.5% dose level. The NOAEL for reproduction was therefore set at the highest dose level which was 0.5% dietary level (250 mg/kg/day).

In a two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg). The control group and the six treated groups comprised of 25 male and 25 female animals. Three of the groups received the compound continuously during the study. In the other three groups the females received the compound only during the 6th through the 15th day of gestation and the males were untreated. No treatment-related changes in behavior or appearance were observed in the parental rats or pups throughout the study. Female rats from the 0.5% continuous treatment group gained slightly less body weight compared to control females. No other consistent differences in body weight were observed. Food consumption was similar for control and treated rats. No compound related differences were seen between control and treated rats with respect to fertility, gestation or viability indices. The average 21-day body weights for pups at the 0.5% continuous treatment group were significantly lower as compared to the average pup

body weights in the controls. No other compound-related changes in body weight were observed. None of the deaths of parental rats during the study was considered to be compound-related. Examination of organ weight values revealed that compound-related effects were limited to increased group mean relative liver weights of male and female F1 from the 0.5% continuous feeding group at the 91-day sacrifice, and increases in group mean relative liver weights of males from the 0.5% continuous feeding group of the F2 generation at the 60-day and caesarean section sacrifices. No compound-related histopathological lesions were observed in any of the tissues examined from rats for the F0 and F1 generations. The NOAEL for reproductive toxicity is at least 0.5% in the diet (250 mg/kg/day).

Developmental Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg/day). General behavior, appearance and survival were not affected by treatment. At the 0.5% dose level, adults and pups gained less weight than the control rats. In the 0.5% dose group, there was a statistical increase in embryo lethality and soft tissue anomalies and at the 0.1% there was a statistical decrease in mean fetal liver weight. Neither of these effects was considered to be treatment-related by the authors as they showed no dose response characteristics. The NOAEL for maternal toxicity is 50 mg/kg/day. The NOAEL for developmental and teratogenicity is 0.1% (50 mg/kg/day).

Pregnant rabbits were given by oral gavage 0, 50, 100 or 200 mg/kg C12AE6 from GD 2 to16. Nine control rabbits and 31 treated rabbits died during the study. Surviving rabbits at the 200 mg/kg dose level generally showed slight losses of body weight. At 100 and 200 mg/kg, ataxia and a slight decrease in body weight was observed in the pregnant animals. In seven treated and two control rabbits early deliveries were recorded. There were no treatment-related effects on corpora lutea, implantations, number of live fetuses and spontaneous abortions. The NOAEL for maternal toxicity is 50 mg/kg/day; the NOAEL for developmental toxicity is 200 mg/kg/day.

In two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 and 0.5% (about 0, 25, 50 and 250 mg/kg). On the 13th day of the gestation period a representative number of female rats from each treatment group of the FC generation (*i.e.*, pups from the 3rd mating of the F0 and F1 parental generation) were sacrificed. Laparotomies were performed and the uterus was examined for uterine abnormalities, normal implantation and resorption sites. Remaining females were sacrificed on the 21st day of gestation. Various maternal and fetal parameters showed occasional values that were significantly different from the corresponding controls. However these were not considered related to the material tested as none occurred at the high feeding level and no dose response for these parameters was apparent. With respect to body weight gains, parental female rats and pups of the high dose group did not gain as much body weight as the control rats. Examination of organ weight values reveal compound related effects were limited to increased group mean liver weighs of male and female P1 generation from the 0.5% continuous feeding group at the

91 day sacrifice and increase in group mean relative liver weights of males of the 0.5% continuous feeding group of the P2 generation at the 60 day section sacrifices. T he NOAEL for maternal and developmental toxicity was established at the 0.1% in the diet (50 mg/kg/day).

Key Study/Critical Effect for Screening Criteria

AEs of different structures with regard to the length of the alkyl chain and the degree of ethoxylation have been evaluated in a number of 90-day and two-year oral toxicity studies. The lowest NOAEL of AEs for systemic toxicity was established at 50 mg/kg/day in two chronic (two-year) dietary studies on C12-13AE6.5 and C14-15AE7. Effects observed at the LOAEL were related to significantly elevated organ-to-body weight ratios for liver, kidney and heart, although there were no adverse histopathological changes.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 50/100 = 0.5 mg/kg/day

Drinking water guidance value = 1.8 ppm

Toxicity Profile

Calcium chloride
(CAS No. 10043-52-4)

Calcium chloride has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Calcium chloride is easily dissociated into calcium and chloride ions in water. The absorption, the distribution and the excretion of the ions in animals are regulated separately. Once calcium chloride is taken up, the effect of the substance on animals should be attributed to the effect of calcium, the effect of chloride, or both.

Calcium and chloride ions are essential constituents of all animals. Absorption, transport, distribution, excretion, and the homeostatic regulation of calcium and chloride ions in animals are well established, as are the mechanisms of action. Calcium is essential for the formation and maintenance of bones and teeth, and for the regulation of various physiological functions such as neural transmission and muscle contraction. Chloride is also essential for the regulation of acid-base balance of the body and intracellular osmotic pressure and acid-base buffering.

Acute Toxicity

The oral LD_{50} values were 2,045 (male) and 1,940 mg/kg (female) in mice, 3,798 (male) and 4,179 mg/kg (female) in rats, and 500-1,000 mg/kg in male rabbits. Acute oral toxicity of the substance is attributed to the severe irritating property of the original compound or its high-concentration solutions to the gastrointestinal tract, causing perforation and ulceration of the contact area of the tract. The dermal LD_{50} value in male/female rabbits was >5,000 mg/kg.

Irritation

Calcium chloride is non to slightly irritating to skin of rabbits; it is, however, severely irritating to eyes of rabbits. Irritating effect of calcium chloride has been observed in human skin injuries caused by the incidental contact with the substance or its high-concentration solutions.

Sensitization

There are no reliable data available for sensitization of calcium chloride.

Repeated Dose Toxicity

Rats (40-day old) were fed 20 mg/g calcium chloride in the diet for 12 months. There were no treatment-related effects on mortality, weight gain, or daily food consumption. In addition, no neoplastic lesions were observed in gastrointestinal tract, urinary tract, liver, heart, brain or spleen of the animals. From the food consumption (22 g diet/day), the daily intake of calcium chloride was estimated to be 440 mg. Considering that 1 mg/g diet is equivalent to 100 and 50 mg/kg/day for young and old rats, respectively, the dose used in this study (20 mg calcium chloride/g diet) corresponds to 1,000 to 2,000 mg/kg/day.

Calcium and chloride are both essential nutrients for humans as well as other animal species. As for healthy humans, the tolerable upper intake level for calcium is set at 2,500 mg per day (equivalent to 6.9 g $CaCl_2$ per day) and the reference nutrient intake for chloride at 2,500 mg/day (equivalent to 3.9 g $CaCl_2$ per day) (U.S Institute of Medicine Dietary Reference Intakes). The estimated intake of calcium chloride as food additives (160-345 mg/day) is considerably smaller than these values. Consistent with this, the establishment of the ADI for calcium chloride has not been deemed necessary by JECFA. The substance has also been considered a GRAS substance by the U.S. FDA. It is thus very unlikely that calcium chloride taken orally as food additives adversely affects human health.

Genotoxicity

In vitro studies for genetic toxicity with sufficient reliability have been reported. Genetic toxicity of calcium chloride was negative in the bacterial mutation tests and the mammalian chromosome aberration test.

Carcinogenicity

No carcinogenicity studies on calcium chloride were located.

Reproductive Toxicity

No reproductive toxicity studies on calcium chloride were located.

Developmental Toxicity

A developmental toxicity study showed no toxic effects on dams or fetuses at doses up to 189 mg/kg/day (mice), 176 mg/kg/day (rats) and 169 mg/kg/day (rabbits).

Key Study/Critical Effect for Screening Criteria

The drinking water guidelines for chloride and hardness (as calcium carbonate) may apply to calcium chloride.

Toxicity Profile

Cocoamidopropyl betaine
(CAS No. 61789-40-0)

Cocoamidopropyl betaine has been reviewed in the OECD-SIDS program (OECD, 2006).

Acute Toxicity

The acute toxicity of cocoamidopropyl betaine (30-35.5% aqueous solution) in rats is low. The oral LD_{50} is $\geq$4,900 mg/kg, and the dermal LD_{50} is >2,000 mg/kg.

Irritation

A 30% aqueous solution of cocoamidopropyl betaine was only very slightly irritating to the skin of rabbits. In human studies, up to 3% solutions were weakly irritating. A 5-10% solution of cocamidopropyl betaine produced mild to moderate irritation to the eyes of rabbits; solutions containing 15% were irritating to highly irritating; and a 30% aqueous solution was irritating with irreversible damage.

Sensitization

The sensitizing potential of cocoamidopropyl betaine in humans is low. Commercial cocoamidopropyl betaine may, however, contain impurities identified as sensitizers (amidoamine and/or 3-dimethylaminopropylamine) which may explain positive results in human patch tests. There is no evidence for a photosensitizing potential.

Repeated Dose Toxicity

Rats were given a 30% aqueous solution of cocoamidopropyl betaine by oral gavage at doses of 0, 250, 500 or 1,000 mg/kg/day (corresponding to about 0, 75, 150, and 300 mg active substance/kg/day, respectively) 5 days/week for 28 days (Henkel KgA, 1991). The only treatment-related findings were forestomach lesions at the highest dose level, probably as a result of the irritant effect of the test substance. The NOAEL for this study is 500 mg/kg/day (150 mg cocoamidopropyl betaine/kg/day).

Rats were given a 30% aqueous solution of cocoamidopropyl betaine by oral gavage at doses of 0, 250, 500 or 1,000 mg/kg/day (corresponding to about 0, 75, 150, and 300 mg active substance/kg/day, respectively) five days/week for 90 days (Th. Goldschmidt AG, 1991). The only treatment-related findings were forestomach lesions at the 500 and 1,000 mg/kg dose levels , probably as a result of the irritant effect of the test substance. The NOAEL for this study is 250 mg/kg day (75 mg cocoamidopropyl betaine/kg/day).

Genotoxicity

There is no evidence for a genotoxic potential of cocoamidopropyl betaine. A 30% aqueous solution of cocoamidopropyl betaine was not genotoxic i*n vitro* in either a bacteria mutation test or in a mouse lymphoma test. A limited intraperitoneal mouse micronucleus test with 27 % active cocamidopropyl betaine was negative.

Carcinogenicity

No valid carcinogenicity studies have been conducted.

Reproductive Toxicity

No reproductive toxicity studies have been conducted on cocoamidopropyl betaine. However, there was no evidence of an adverse effect on the reproductive organs in rats given oral doses of up to 1,000 mg/kg/day of a 30% aqueous solution of cocoamidopropyl betaine (300 mg active substance/kg/day) for 90 days (Th. Goldschmidt AG, 1991).

Developmental Toxicity

A 28.9% aqueous solution of cocoamidopropyl betaine was tested in a rat developmental toxicity at doses of 330, 990, and 3,300 mg/kg/day (corresponding to 95, 286, and 950 mg/kg/day, respectively) (CESIO, 2004). There were dose-related maternal toxic effects (reduced body weights and stomach ulcers) at 990 mg/kg/day and above. Embryotoxic effects (increased numbers of resorptions, decreased number of viable fetuses, decreased fetal body weight) were found only at the maternal toxic dose level of 3,300 mg/kg/day. The NOAEL for maternal toxicity was 330 mg/kg/day (corresponding to 95 mg active substance/kg-day) and the NOAEL for developmental toxicity was 990 mg/kg/day (corresponding to 286 mg active substance/kg/day).

Key Study/Critical Effect for Screening Criteria

The key study is a 90-day rat oral gavage study in which forestomach lesions were seen at dose levels of 500 and 1,000 mg/kg of a 30% aqueous solution of cocoamidopropyl betaine. The NOAEL for this study is 250 mg/kg/day (75 mg active substance/kg/ay).

$NOAEL_{adjusted}$ = 75 * 5/7 = 53.6 mg/kg/day

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 0.05 mg/kg/day

Toxicity Profile

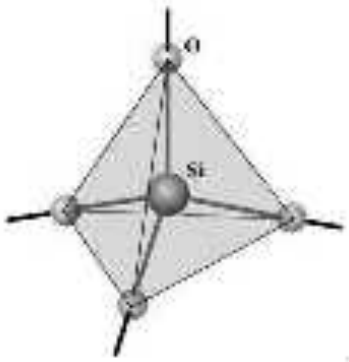
Crystalline Silica, Cristobalite
(CAS No 14464-46-1)

Crystalline Silica, Quartz
(CAS No. 14808-60-7)

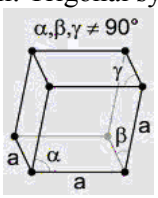
Silica is an off-white granule that occurs naturally in various crystalline and amorphous or other non-crystalline forms. Crystalline silica is characterized by silicon dioxide (SiO_2) molecules oriented in fixed, periodic patterns to form stable crystals. The primary crystalline form of silica is quartz. Other crystalline forms of silica include cristobalite, tripoli and tridymite. Particle size is a key determinate of silica toxicity, since toxicity is restricted to particles that are small enough to be deposited into the target regions of the respiratory tract.

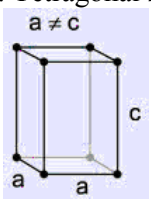
Oral Exposure

No oral studies were located; however, crystalline silica is not expected to exhibit toxicity by the oral route. Although absorption studies were not found for crystalline silica, kinetic studies on amorphous silica show no absorption from the gastrointestinal tract.



Dermal Exposure





No dermal studies were located; however, crystalline silica is not expected to exhibit toxicity by the dermal route.

Inhalation Exposure

See attached OECD-SIDS Initial Targeted Assessment Profile on Quartz and Cristobalite, SIAM 32, 19-21 April 2011.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

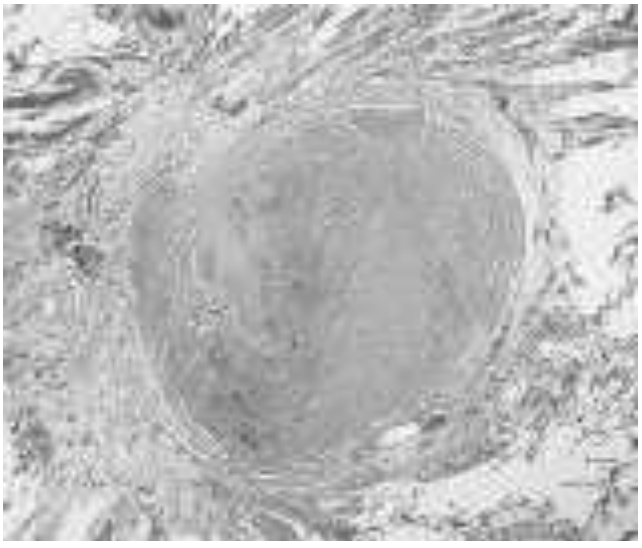


Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3
Sister chromatid exchange	0/1		0/1[c]	1/1	0/2	1/1
Micronucleus	2/3	0/1	2/2[b]	1/1	4/5	1/2

Cell transformation	4/4				4/4	
Hprt mutation	1/2	2/2[a]	1/1[b]		2/3	2/2
Oxidative DNA damage		4/5	2/2		2/2	4/5
DNA binding		1/1				1/1
p53 activation		0/1				0/1

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

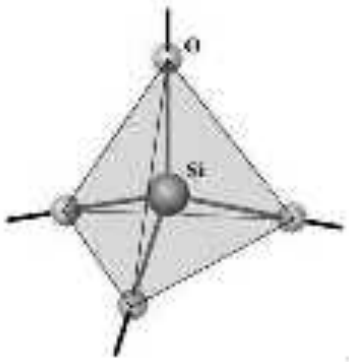
bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

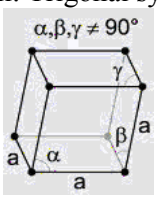
Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

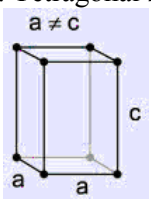
Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.



OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.





RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

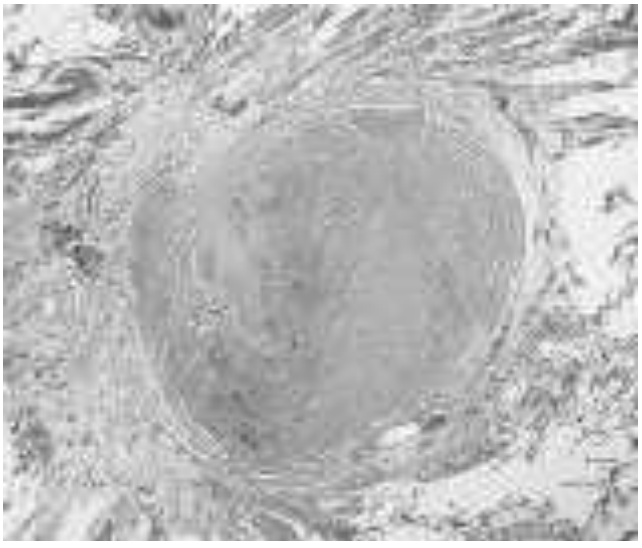

Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.

OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.

RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

Toxicity Profile

Endo-1,4-beta-Mannanase
(CAS No. 37288-54-3)

No data could be located on endo-1,4-beta-mannanase. There is information, however, on α-amylases. α-Amylase catalyzes the endo-hydrolysis of 1,4-α-D-glycosidic linkages in polysaccharides like starches, glycogen, and oligosaccharides containing three or more 1,4-α-linked glucose units. Given the similarity of the substrates, amylases and endo-1,4-beta-mannanase would be expected to have similar physico-chemical properties relevant to evaluating their mammalian toxicity potential.

The data on α-amylases have come from detergent amylases, the typical ones being *Bacillus*, which has an neutral isoelectric point and a broad pH optimum between pH 5 and 9. The enzyme is characterized by a molecular weight of 58 kD (HERA, 2005).

Acute Toxicity

No deaths were observed when male and female rats were given an aqueous suspension of 0, 4,000 or 10,000 mg/kg of α-amylase ("salt free" batch PPY 1316, enzyme derived from *B. subtilis*) by oral gavage. The actual enzyme content of this batch was 239 mg aep/g. In another study, male and female rats were given an aqueous suspension of 0 or 5,000 mg/kg α-amylase preparation derived from *B. licheniformis*, the actual enzyme content of the preparation was 60.13 mg aep/g. There were no deaths.

Rats were exposed by inhalation to either 1.6 mg/L of a production α-amylase (from *B. subtilis*) batch ADTA 202-204, a mixture of two batches prepared by the standard production process (45.9% of particles <4.7 μm) or 1.08 mg/L of a "salt-free" α-amylase (from *B. subtilis*) batch PPY 1316, prepared from production batch ADTA 202-204 by removal of NaCl (33.3% of particles <4.7 μm), for 4 hours. An air-exposed control group was also included. The actual amount of enzyme protein in the test aerosols was 0.114 mg aep/L (production batch) and 0.258 mg aep/L (salt-free batch). There were no deaths occurred. In another study, rats were exposed to 1.6 mg/L α-amylase (from *B. subtilis*) preparation (highest concentration attainable) derived from a genetically modified strain of *B. subtilis* for 4 hours. Total organic solids comprised 83.3% of the test substance (active and inactive enzyme as well as other organic material). There were no deaths (HERA, 2005).

Irritation

α-Amylase (from *B. subtilis*) has a low potential for irritation to the skin and eyes of rabbits (HERA, 2005). In a human repeat insult patch test (HRIPT), although skin irritation did not appear after a single application, irritation was reported in human

volunteers receiving nine topical applications of 1, 2.5, 5 or 10% α-amylase (from *B. subtilis*) in distilled water. The magnitude of responses increased with increasing concentration such that the use of the 10% concentration was discontinued and was replaced for the rest of the study by a 0.5 % α-amylase. The irritation was thought to be due to residual protease activity present in the amylase preparation (HERA, 2005).

Sensitization

α-Amylase (from *B. subtilis*) was not a skin sensitizer to guinea pigs in two different studies (HERA, 2005). In a human repeat insult patch test (HRIPT) reported above, there were no significant reactions indicative of skin sensitization in the challenge phase (HERA, 2005).

Repeated Dose Toxicity

Rats and dogs have been given amylase enzymes orally for up to 90 days. These studies were not reported in any detail and the actual amount of enzyme in the formulations tested in these studies is unclear. No findings of toxicological significance were observed in either species exposed to any of the α-amylase formulations tested other than "slight" reductions in food consumption at high dietary doses ($\geq$5% of the diet) or irritation of the stomach of rats dosed by oral gavage with $\geq$3,000 mg/kg/day (HERA, 2005).

Genotoxicity

α-Amylase (from *B. licheniformis* and from *B. subtilis*) was not mutagenic to *S. typhimurium* strains TA 1535, TA 1537, TA 98, TA 100 in bacterial reverse mutation assays in the presence or absence of metabolic activation (HERA, 2005). α-Amylase (from *B. licheniformis*) did not induce chromosome aberrations in human lymphocytes, which were obtained from one donor only (HERA, 2005). It was also inactive when tested in an *in vivo* bone marrow chromosomal aberrations study, in which rats were dosed orally up to 5,000 mg/kg (HERA, 2005).

Carcinogenicity

No data were found.

Reproductive/Developmental Toxicity

Two α-amylases, one derived from *B. stearothermophilus* and one derived from a genetically modified strain of *B. subtilis* have been evaluated for effects on fertility in one-generation studies in rats. The diets containing 0, 36 or 72 units of α-amylase/g

food. No treatment-related effects on fertility or other findings of toxicological significance were observed for either enzyme.

Key Study/Critical Effect for Screening Criteria

Oral studies (dietary and/or oral gavage) up to 90 days on α-amylase have been conducted in rats and dogs. These studies have been poorly reported. Slight reductions in food consumption was reported at ≥5% in the diet (2,500 mg/kg/day in rats) and irritation of the stomach of rats dosed with ≥3,000 mg/kg/day. These studies are considered unreliable because of the lack of reported key information needed for risk assessment purposes.

There is, however, a 13-week rat dietary study conducted on a cellulase enzyme (HERA, 2005). The cellulase enzymes cleave the ß-1,4-glycosidic bonds in cellulose. For the purposes of risk assessment, the structure of amylases would be expected to be relatively similar to that of celluloses, given that amylases and cellulases are both enzyme families that hydrolyze polysaccharides, although differing in their substrates. Thus, the toxicity data on cellulases will be used as read-across to amylases for the repeat dose toxicity endpoint.

In the 13-week dietary study on a cellulase enzyme, there was reduced body weight gain in rats given 3,000 mg/kg/day. No other adverse effects were observed. The NOAEL for this study is 600 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 600/1000 = 0.6 mg/kg/day

Drinking water guidance value = 2.1 ppm

Toxicity Profile

Ethanol
(CAS No. 64-17-5)

Ethanol has been reviewed in the OECD-SIDS program (OECD, 2004a,b).

Acute Toxicity

Ethanol has a low order of acute toxicity by all routes of exposure. The lowest well-conducted acute oral LD_{50} value is 8,300 mg/kg in mice, and an inhalation 1-hour LC_{50} value of >60,000 ppm (114,000 mg/m^3) in mice.

Irritation

Ethanol is a moderate eye irritant but it is not a skin irritant.

Sensitization

Ethanol is not a sensitizer.

Repeated Dose Toxicity

There are numerous repeat dose toxicity studies on ethanol by the oral route. Many of these studies were designed to increase our understanding of the risks associated with alcoholic beverages. Thus, these studies were carried out by the oral route and at high doses. The selected studies were considered appropriate for risk assessment purposes.

In a 90-day study, male and female Sprague-Dawley rats were fed a diet containing 0, 1, 2, 3, 4, 5 or 10% ethanol. The 2% dose was calculated to be equivalent to 2,400 mg/kg/day. There were no deaths and no clinical signs of noted. Weight gain throughout the study was unaffected by treatment, but the final weights decreased with dose. Food and water consumption in the 10% group was reduced relative to controls. There was no treatment-related effect on serum liver enzymes and kidney clinical chemistry findings were minimal. In the liver, centrilobular steatosis increased in severity with dose as did the frequency and severity of Mallory bodies (hyaline) and acidophilic degeneration and necrosis. Most liver findings were absent or mild at 2% ethanol but became more significant at $\geq$3%. The NOAEL for this study has been established to at 2% (2,400 mg/kg/day).

In an NTP 90-day study, F344/N rats and $B6C3F_1$ mice were given in their drinking water 0 or 5% ethanol in drinking water. Based on the water consumption data in the

study and averaged body weights over the exposure period, this equated to doses of at least 4,000 mg/kg in rats and 7.500 mg/kg in mice. Male rats showed minor changes to organ weights and hematology and clinical chemistry parameters (these were not considered to be adverse changes); female rats showed minor clinical chemistry changes and increased length of estrus cycle, as well as liver nodules. The male mice showed increased organ weights, fatty changes to the liver, and a decrease in sperm concentration.

In the NTP two-year bioassay, B6C3F$_1$ mice were given in their drinking 0, 2.5% and 5% ethanol Concentrations of 2.5% and 5% ethanol resulted in average daily consumption of approximately 100 and 180 mg ethanol for males and 80 and 155 mg for females. There was a marginal exposure-related increase in survival of the males, but no effect on the survival of the females. Water consumption was reduced with increasing concentrations of ethanol which was more marked in males than females. No further information was given on non-neoplastic effects.

Genotoxicity

The balance of evidence is that ethanol is not genotoxic. Negative results from a number of bacterial mutation assays appear to be reliable. Of the mammalian cell mutation assays a weak mutagenic effect in mouse lymphoma cells occurred only at very high ethanol concentrations. *In vivo* tests for chromosome aberrations in both rats and Chinese hamsters have given negative results. There is very little evidence to suggest that ethanol is genotoxic in somatic cells and it may have a very limited capacity to induce genetic changes *in vivo* but under very specific circumstances and at very high doses achievable in humans only by deliberate oral ingestion.

Carcinogenicity

Evidence of the carcinogenicity of ethanol is confined to epidemiological studies assessing the impact of alcoholic beverage consumption. These do not indicate any such hazard exists from potential exposure to ethanol in the work place or from the use of ethanol in consumer products.

Reproductive/Developmental Toxicity

The lowest reported NOAEL for fertility by the oral route was 2,000 mg/kg in rats, equivalent to a blood alcohol concentration of 1,320 mg/L, although this was based on a significant increase in the number of small pups rather than a direct effect on fertility; such direct effects are not seen until much higher doses. Many studies exist examining the developmental end point for ethanol. However, most use very high doses and few are individually robust enough to allow a NOAEL to be established. However, the collective weight of evidence is that the NOAEL for developmental effects in animals is high,

typically >6,400mg/kg, compared to maternally toxic effects at 3,600 mg/kg. The potential for reproductive and developmental toxicity exists in humans from deliberate over-consumption of ethanol. Blood ethanol concentrations resulting from ethanol exposure by any other route are unlikely to produce reproductive or developmental effects.

Key Study/Critical Effect for Screening Criteria

The lowest reported NOAEL is approximately 2,400 mg/kg/day from a 90-day dietary study with rats.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 2,400/1,000 = 2.4 mg/kg/day

Drinking water guidance value = 8.4 ppm

Toxicity Profile

Ethoxylated Fatty Acid Ester II

This substance is a hydrophilic, non-ionic surfactant used in pharmaceutical preparations, and cosmetics as an emulsifier, dispersant, or stabilizer, and as a food additive. It is considered a mixture and thus a UVCB substance (substance of unknown or variable composition, complex reaction products or biological materials).

Acute Toxicity

Reported oral LD_{50} values for rats range from approximately 33,800 mg/kg to approximately 54,500 mg/kg, while the oral LD_{50} for mice is greater than 25,000 mg/kg. Clinical experience with humans who have ingested large quantities of this substance indicates that it is essentially nontoxic by the oral route, with the estimated lethal dose being 15,000 mg/kg.

Irritation

In 24-hour rabbit skin-patch tests, this substance was found to produce minimal or no irritation. Daily application of 100% solutions of this substance to the backs of rabbits for 30 days produced histologic changes in the skin, including mild to moderate inflammation, acanthosis, and necrosis. Application of 1% or 2.5% aqueous solutions of this substance to the backs of mice for up to 9 days produced no gross or microscopic lesions. Studies conducted in humans did not result in skin irritation.

Sensitization

Repeated intradermal injections of this substance into guinea pigs did not produce skin sensitization, and studies conducted in humans did not result in sensitization.

Repeated Dose Toxicity

In a multi-generation study, doses of 5%, l0%, and 20% of test material were administered in the feed to male and female rats. Composition of the diet was altered for different dose levels to compensate for the decrease in caloric value caused by addition of the test material. Diarrhea was seen in animals fed 10% or 20% test substance, and was presumably due to the osmotic effect of the large amounts of polyoxyethylene moiety in the intestinal tract. There was some reduction in growth rate, postnatal survival of pups, lactation and breeding efficiency, and longevity in rats fed the diet containing 20% test material. Hematologic examination showed no abnormalities and no treatment-related histologic lesions were seen upon examination of kidneys, livers, and gross lesions. No

significant findings were reported in a three-generation study using groups of 30 rats fed 2% test substance. Degeneration of the heart, liver, and kidney were reported in groups of 12 Charles Foster rats administered a daily dose of 1.5 mL of a solution of 1%, 2%, or 3% test substance for 3 months. Similar effects were not reported in other studies using higher doses for longer periods, so the significance of the findings of this single study is debatable. Daily administration of 1g of this substance to each of two monkeys for 17 months produced no compound-related gross or microscopic lesions.

Evidence indicates that the long-term ingestion of this substance by humans does not result in toxicity. Long-term consumption (one or more years) of 4.5 to 6 g of this substance per day by human patients for the treatment of lipid malabsorption syndromes has been reported to cause no adverse effects. The consumption of doses as high as 15 g/day for several months caused no clinical indications of toxicity.

Groups of 10 F344/N rats and 10 B6C3F_1 mice of each sex received diets containing 0, 3,100, 6,200, 12,500, 25,000 or 50,000 ppm test material. All animals survived to the end of the studies. The final mean body weights of dosed rats and mice were similar to those of the controls. No clinical findings, changes in absolute or relative organ weights, or gross or microscopic lesions in rats or mice were related to test material administration. The NOAEL is 50,000 ppm.

Genotoxicity Studies

This substance is not genotoxic is a variety of in vitro and in vivo assays.

Carcinogenicity studies

In one study, 28 mice were fed diets containing 10 mg of this substance daily for 51 week, no neoplasms occurred as the result of treatment.

Groups of 60 F344/N rats and 60 B6C3F_1 mice of each sex received diets containing 0, 25,000, or 50,000 ppm test material for up to 103 weeks. Interim evaluations were performed on 7 to 10 rats and mice from each dose group at 15 months. There were no significant changes in absolute or relative organ weights. Incidences of hyperplasia and inflammation of the forestomach were increased in female mice that received 50,000 ppm. No other chemical-related lesions occurred in rats or male mice evaluated at 15 months.

The mean body weights in male and female rats and male mice administered test material were similar to those of the controls throughout the studies. The final mean body weight of female mice receiving 50,000 ppm was 11% lower than that of the controls. No clinical findings were associated with administration of test material. The survival of dosed male rats was lower than that of the controls (0 ppm, 29/50; 25,000 ppm, 18/50; 50,000 ppm, 18/50); the survival of dosed female rats and male and female mice was

similar to that of the respective controls (female rats: 23/50, 25/50, 25/50; male mice: 33/49, 34/50, 32/50; female mice: 30/50, 28/50, 26/50).

The incidence of adrenal medulla pheochromocytoma was marginally increased in high-dose male rats (21/50, 19/50, 29/50). The slight increase in incidence of pheochromocytoma in the high-dose male rat group was judged to be of questionable significance based on historical control data. The incidence of hyperplasia of the adrenal medulla was increased in low-dose male rats but not in high-dose male rats (11/50, 22/50, 12/50). The marginal increased incidence of pheochromocytoma in combination with the increased incidence of hyperplasia were considered to be an equivocal finding.

No chemical-related increases in the incidences of neoplasms occurred in male or female mice. The incidences of squamous hyperplasia and inflammation of the forestomach were significantly increased in high-dose male and female mice; forestomach ulcers were significantly increased in high-dose females.

Developmental Toxicity

Timed-mated Sprague-Dawley rats were exposed to 0, 500 or 5,000 mg/kg/day of test material on gestational days (GD) 6 through 15. All treated females survived to scheduled necropsy and 19-23 pregnancies per group were confirmed. No dose-related signs of toxicity were observed for individual animals during the in-life phase of the study or at scheduled necropsy. Average maternal body weight (GD 0, 3, 6, 9, 12, 15, 18, or 20) did not differ among treatment groups, nor was there a treatment-related change in maternal weight gain during treatment or gestation (absolute or corrected). There were no treatment-related effects upon the following maternal organ weights: gravid weight (absolute), kidney weight (absolute or relative), and heart weight (absolute or relative). Relative maternal liver weight (% body weight on GD 20 or % corrected body weight) was elevated in both treated groups and absolute liver weight was elevated at 500 mg/kg/day. Maternal food intake was comparable across groups during the pre- and post-treatment periods, but was decreased by 14% during the first 3 days of treatment at 5,000 mg/kg/day relative to the vehicle control group. Maternal relative water intake was comparable among treatment groups throughout gestation. No differences among groups were noted for the number of corpora lutea per dam, the number of implantation sites per dam or the percent preimplantation loss per litter. No adverse effects were noted on the growth, viability or morphological development of the conceptuses. In conclusion, the maternal LOAEL was 500 mg/kg/day (based upon an increase in maternal relative liver weight). No definitive adverse effects of test material upon prenatal development were noted in this study. Thus, the developmental NOAEL was greater than 5,000 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

Compound-related lesions of the forestomach occurred in all dosed mouse groups in a two-year feeding study. These included squamous hyperplasia of the epithelium,

inflammation, and, in high-dose females, ulcers. It was suggested that this substance ,as a surfactant, produced forestomach injury by localized irritation to the epithelial cells.

LOAEL = 25,000 ppm in mice (forestomach lesions)

LOAEL (mg/kg/day) = 25,000 ppm * 0.13 = 3,250 mg/kg/day

Where 0.13 is the fraction of body weight that is consumed per day as food for the mouse (U.S. EPA).

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (LOAEL to NOAEL)

Oral RfD = 3,250/1,000 = 3.25 mg/kg/day

Drinking water guidance value = 11.4 ppm

Toxicity Profile

Ethoxylated Sorbitan Monooelate
Polysorbate 80
(CAS No. 9005-65-6)

Ethoxylated sorbitan monooleate or polysorbate 80 is a hydrophilic, non-ionic surfactant used in pharmaceutical preparations, and cosmetics as an emulsifier, dispersant, or stabilizer, and as a food additive. It is a mixture of oleic esters of sorbitan and its anhydrides copolymerized with approximately 20 mol of ethylene oxide (Sweetman, 2002). Thus, polysorbate 80 is considered a UVCB substance (substance of unknown or variable composition, complex reaction products or biological materials).

The information below and the references can be found in NTP (1992a).

Metabolism

The metabolism of radiolabeled polysorbates in rats has been studied. After oral administration, the ester linkage of the polysorbate molecule is hydrolyzed by pancreatic lipase and the released fatty acid is absorbed and metabolized; essentially all of the fatty acid in polysorbate 80 fed as 10% of the diet is hydrolyzed and absorbed. The sorbitol-polyoxyethylene moiety is poorly absorbed and most is excreted in the feces. In metabolism studies conducted with rats fed polysorbate 80 containing radiolabeled sorbitol, 91% of the radioactivity was found in the feces, 2.1% was found in the urine, and 1.6% was found in the carcass. None was found in the liver, kidney, adrenal glands, spleen, brain, or fat. Following intravenous administration of polysorbates to rats, the ester linkage of the polysorbates is hydrolyzed by blood lipases. Intravenous studies using radiolabeled polysorbate 20 in rats demonstrated that the fatty acid portion was metabolized and excreted mostly as expired carbon dioxide, with lesser amounts appearing in the urine and feces; the sorbitol-polyoxyethylene moiety was not catabolized and was excreted mainly in the urine, although a small amount was found in the feces, indicating some biliary excretion; trace amounts were detected in the carcass and liver.

Metabolism of polysorbates in humans appears to be similar to that in rats. Analysis of urine and feces from human volunteers who consumed 4.5 g of polysorbate 80 daily showed that 95% of the polyoxyethylene portion was excreted in the feces and 5% in urine; apparently, none was retained in the body.

Acute Toxicity

Reported oral LD_{50} values for rats range from approximately 33,800 mg/kg to approximately 54,500 mg/kg, while the oral LD_{50} for mice is greater than 25,000 mg/kg. Clinical experience with humans who have ingested large quantities of polysorbate 80 indicates that the compound is essentially nontoxic by the oral route, with the estimated lethal dose being 15,000 mg/kg.

Irritation

In 24-hour rabbit skin-patch tests, polysorbate 80 was found to produce minimal or no irritation. Daily application of 100% solutions of polysorbate 80 to the backs of rabbits for 30 days produced histologic changes in the skin, including mild to moderate inflammation, acanthosis, and necrosis. Application of 1% or 2.5% aqueous solutions of polysorbate 80 to the backs of mice for up to 9 days produced no gross or microscopic lesions. Studies conducted in humans did not result in skin irritation.

Sensitization

Repeated intradermal injections of polysorbate 80 into guinea pigs did not produce skin sensitization, and studies conducted in humans did not result in sensitization.

Repeated Dose Toxicity

In a multi-generation study, doses of 5%, l0%, and 20% polysorbate 80 were administered in the feed to male and female rats. Composition of the diet was altered for different dose levels to compensate for the decrease in caloric value caused by addition of polysorbate 80. Diarrhea was seen in animals fed 10% or 20% polysorbate 80, and was presumably due to the osmotic effect of the large amounts of unabsorbed sorbitol-polyoxyethylene moiety in the intestinal tract. There was some reduction in growth rate, postnatal survival of pups, lactation and breeding efficiency, and longevity in rats fed the diet containing 20% polysorbate 80. Hematologic examination showed no abnormalities and no treatment-related histologic lesions were seen upon examination of kidneys, livers, and gross lesions. No significant findings were reported in a three-generation study using groups of 30 rats fed 2% polysorbate 80. Degeneration of the heart, liver, and kidney were reported in groups of 12 Charles Foster rats administered a daily dose of 1.5 mL of a solution of 1%, 2%, or 3% polysorbate 80 for 3 months. Similar effects were not reported in other studies using higher doses for longer periods, so the significance of the findings of this single study is debatable. Daily administration of 1g polysorbate 80 to each of two monkeys for 17 months produced no compound-related gross or microscopic lesions.

Evidence indicates that the long-term ingestion of polysorbate 80 by humans does not result in toxicity. Long-term consumption (one or more years) of 4.5 to 6 g polysorbate 80 per day by human patients for the treatment of lipid malabsorption syndromes has been reported to cause no adverse effects. The consumption of doses as high as 15 g/day for several months caused no clinical indications of toxicity.

Groups of 10 F344/N rats and 10 $B6C3F_1$ mice of each sex received diets containing 0, 3,100, 6,200, 12,500, 25,000 or 50,000 ppm polysorbate 80. All animals survived to the

end of the studies. The final mean body weights of dosed rats and mice were similar to those of the controls. No clinical findings, changes in absolute or relative organ weights, or gross or microscopic lesions in rats or mice were related to polysorbate 80 administration. The NOAEL is 50,000 ppm (NTP, 1992a).

Genotoxicity Studies

Polysorbate 80 is not genotoxic is a variety of in vitro and in vivo assays.

Carcinogenicity studies

In one study, 28 mice were fed diets containing 10 mg polysorbate 80 daily for 51 week, no neoplasms occurred as the result of treatment.

Groups of 60 F344/N rats and 60 B6C3F mice of each sex received diets containing 0, 25,000, or 50,000 ppm polysorbate 80 for up to 103 weeks. Interim evaluations were performed on 7 to 10 rats and mice from each dose group at 15 months. There were no significant changes in absolute or relative organ weights. Incidences of hyperplasia and inflammation of the forestomach were increased in female mice that received 50,000 ppm. Toxicity Profile

Fatty Acid Ester

This fatty acid ester is a non-ionic surfactant-active agent that typically finds use as an emulsifier, stabilizer and thickener in foods, cosmetics, medical products, and lubricants, and other applications. It is approved by FDA as an indirect food additive.

Acute Toxicity

The acute oral LD_{50} of this substance in rats was reported to be > 39,800 mg/kg.

Irritation

No data were located.

Sensitization

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Oral feeding toxicity studies have been carried out in rats for 16 weeks with this substance at dietary concentrations of 0, 2.5, 5 and 10%. The LOAEL was 2.5% dietary concentration (~1800 mg/kg/day) based on increased kidney weight findings that were considered significant in both male and female rats.

This substance fed to rats at 5% concentrations in the diet for 2 years showed no adverse effects on growth, hematology, clinical chemistry, survival, organ size or histopathology. The NOAEL was reported to be 5% in the diet.

Genotoxicity

No genotoxicity studies could be located for this substance; however, there are two studies conducted on a structurally similar substance.

The surrogate was not mutagenic to *Salmonella typhimurium* TA98 and TA100 in a Ames mutation assay in the presence or absence of metabolic activation. It did not cause any chromosomal aberrations in the Syrian golden hamster embryo cell assay and did not show clastogenic activity.

Reproductive/Developmental Toxicity

No studies could be located for this substance; however, there is one study conducted in a structurally similar substance.

The surrogate was administered in the diet at dose levels of 0, 5, 10, and 20% over a period of two years and over four generations of rats. No effects were observed on growth, food efficiency, reproduction, lactation, metabolism, behavior, mortality, or in the gross and histopathological examination. At the 20% dose level in the diet, newborn mortality was not increased but there were slight effects on growth and impairment of lactation.

Key Study/Critical Effect for Screening Criteria

No treatment-related effects were noted in a two-year carcinogenicity study in which rat were fed this fatty acid ester in the diet at concentrations up to 5% (50,000 ppm).

NOAEL (mg/kg/day) = 50,000 ppm * 0.05 = 2,500 mg/kg/day

Where 0.05 is the fraction of body weight that is consumed per day as food for the rat (U.S. EPA).

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 2,500/100 = 25 mg/kg/day

Drinking water guidance value = 87.5 ppm

Toxicity Profile

Guar Gum
(CAS No. 9000-30-0)

Guar gum (CAS No. 9000-30-0) is the milled endosperm of the leguminous plant *Cyanopsis tetragonolobus*. Structurally, it is a galactomannan consisting of a main chain of D-mannose with a side chain of D-galactose at approximately every second mannose unit. The mannose units are β-(l-4) linked, and the single D-galactose units are joined to the main chain by α-(1-6) linkages. The estimated molecular weight of guar gum cranges from 200,000 to 300,000 daltons (Glickman, 1969).

Guar gum is approved for use as a food additive by the U.S. Food and Drug Administration and is on the list of substances "generally recognized as safe" (CFR 1974).

Acute Toxicity

The oral LD_{50} is 8,100 mg/kg for mice and 9,400 mg/kg for rats (Bailey and Morgareidge, 1948).

Irritation

No data were found.

Sensitization

There are reports of respiratory sensitization in workers exposed occupationally to guar gum dusts (Maio, 1986).

Repeat Dose Toxicity Studies

F344 rats and B6C3F_1 mice were given diets containing 0, 6,300, 12,500, 25,000, 50,000 or 100,000 ppm guar gum for 13 weeks (NTP, 1982). Mean body weights were decreased in male rats (100,000 ppm group) and in female mice (50,000 and 100,000 ppm). A dose-related decrease in feed consumption was observed for male and female rats; male and female mice were comparable or higher than that of controls. There were no compound-related clinical signs or histopathological effects.

F344 rats and B6C3F_1 mice were given diets containing 0, 25,000 ppm or 50,000 ppm guar gum for 103 weeks (NTP, 1982). Mean body weights of the high-dose females were

lower than those of the controls after week 20 for mice and week 40 for rats. No compound-related clinical signs or adverse effects on survival were observed. Feed consumption by dosed rats and mice of either sex was lower than that of controls. There were no non-neoplastic histopathological effects in either rats or mice that were treatment-related.

Genotoxicity

Guar gum was not mutagenic to *Salmonella typhimurium* TA 1530 or G-46 when tested without metabolic activation; however, it was mutagenic to *Saccharomyces cerevisiae* D-3 (Green, 1977). Guar gum also was reported to cause chromosomal aberrations in human embryonic lung cells WI-38 (Green, 1977). No *in vivo* genotoxicity studies have been conducted on guar gum.

Carcinogenicity

F344 rats and B6C3F_1 mice were given diets containing 0, 25,000 ppm or 50,000 ppm guar gum for 103 weeks (NTP, 1982). There were increased incidences of adenomas of the pituitary in male rats and pheochromocytomas of the adrenal in female rats that were statistically significant, but these differences were considered to be unrelated to guar gum administration. When pituitary adenomas or carcinomas and when pheochromocytomas or malignant pheochromocytomas are combined, the statistical differences disappear. Hepatocellular carcinomas occurred in treated male mice at incidences that were significantly lower than that in controls. The combined incidence of male mice with either hepatocellular adenomas or carcinomas was also significantly lower in the high-dose group. It was concluded that under conditions of this bioassay, guar gum was not carcinogenic for F344 rats or B6C3F_1 mice.

Reproductive Toxicity

No data were found.

Developmental Toxicity

Female rabbits were given daily (6 hours/day) dermal administration of 0, 2, 10 and 50 mg/kg guar gum during gestational days 6 through 18 (IRDC, 1988). Mortalities included 2 deaths at 50 mg/kg and 1 death at 10 mg/kg. A single animal was killed in extremis. A dose-related increase in dermal irritation (including erythema, edema, and desquamation) was observed in animals receiving 10 and 50 mg/kg. The number of early resorptions was significantly increased and the number of viable fetuses was correspondingly decreased at 50 mg/kg/day ($p<0.05$). The frequency of fetal malformations and variations in the treated groups was comparable to that of the control

group at all dose levels. The NOEL for this study is 2 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The key studies for the determination of a drinking water guidance value is the NTP two-year chronic bioassays. The LOAELs are based on decreased mean body weights in female mice and rats fed 50,000 ppm guar gum in diet for 103 weeks. The NOAELs for these studies are 25,000 ppm guar gum.

Rat: NOAEL (mg/kg/day) = 25,000 ppm * 0.05 = 1,250 mg/kg/day

Mouse: NOAEL (mg/kg/day) = 25,000 ppm * 0.13 = 3,250 mg/kg/day

Where 0.05 and 0.13 are the fraction of body weight that rats and mice, respectively, consume per day as food (U.S. EPA).

The lowest NOAEL of 1,250 mg/kg/day for the rat will be used to derive a drinking water guidance value.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 1,250/100 = 12.5 mg/kg/day

Drinking water guideline = 44 ppm

NTP (1982). NTP Technical Report on the Carcinogenesis Bioassay of Guar Gum (CAS No. 9000-30-0) in F344 Rats and B6C3F_1 Mice (Feed Study), National Toxicology Program, Research Triangle Park, NC

Toxicity Profile

Hydrocarbons, Terpene Processing By-products
(CAS No. 68956-56-9)

Terpenes and Terpenoids, Sweet Orange Oil
(CAS No. 68647-72-3)

CAS No. 68956-56-9 is a by-product of the manufacturing process in which high-quality gum turpentine oil or alpha pinene is synthesized into terpineol. It is largely composed of alpha terpinene, dl-limonene, cineol, gamma terpinene, terpinolene and other terpene hydrocarbons. The composition of CAS No. 68956-56-9 in the HPV Test Plan for Monoterpene Hydrocarbon Category is: 22-34% limonene, 22-33% terpinolene, 5-10% mycene, 18% limonene isomers, 10% other terpene hydrocarbons.

CAS No. 68647-72-3 is composed of 91-95% d-limonene, 1-3% beta-myrcene, and 1-2% alpha-pinene.

Acute Toxicity

The oral and dermal LD_{50} values for limonene, myrcene, terpinolene, dihydromyrcene and sweet orange peel oil indicate a low order of both oral and dermal toxicity. All rabbit and rat dermal, and mouse and rat oral LD50 values are >4,000 mg/kg with the majority of values being >5,000 mg/kg.

Irritation

No data were located.

Sensitization

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Selected repeat dose toxicity studies were included in this toxicity profile. For summaries on all conducted studies, see the U.S. HPVIS.

Groups of ten Sprague Dawley rats of each sex were administered 0, 240, 600 or 1,500 mg/kg sweet orange oil in 1% methyl cellulose by gavage daily for 30 days. Observations included survival, clinical observations, body weights, food consumption, clinical

pathology, gross pathology, organ weights and histopathology. No treatment related effects were reported for survival, clinical observations, body weights or food consumption. Decreases in glucose levels related to treatment were reported in the mid-dose females and high-dose males and females. Increases in serum albumin and total serum protein were observed in all treated females and the high-dose males. Histopathology revealed treatment related lesions in the nonglandular stomach of the high-dose males and females and in the kidney of all treated male groups. Kidney weights were also increased in all of the treated male groups and in the high-dose female group. Liver weight increases related to treatment were reported for the high-dose females and all treated male groups. The authors concluded that the no-observed-effect-level (NOEL) under conditions of this study was less than 240 mg/kg/day for both male and female rats. The authors noted that the kidney changes observed in the male rat at all dose levels were expected given the known interaction between limonene and *alpha*-2-microglobulin. Limonene is the principal constituent of orange oil.

In a NTP 13-week study, male and female F344/N rats were dosed by oral gavage 0, 150, 300, 600, 1,200 or 2,400 mg/kg *d*-limonene in corn oil for 5 days/week. At 2,400 mg/kg, 9/10 female rats and 5/10 male rats (5/10) died within the first week of the study. The final mean body weights of male rats receiving the three highest doses (600, 1,200 or 2,400 mg/kg) were reported to be 6%, 12%, or 23% lower than that of the controls, respectively. Rough hair coats, lethargy, and excessive lacrimation were observed for all animals in the 1,200 and 2,400 mg/kg dose groups. Kidney effects were seen in all treated male rats, with a dose-related increase in severity. The kidney effects were characterized by degeneration of epithelium in the convoluted tubules, granular casts with tubular lumens, primarily in the outer stripe of the outer medulla, and regeneration of the tubular epithelium. Hyaline droplets were observed in the epithelium of the proximal convoluted tubules in all groups of male rats including vehicle controls.

In a NTP 13-week study, male and female $B6C3F_1$ mice were dosed by oral gavage with 0, 125, 250, 500, 1,000 or 2,000 mg/kg *d*-limonene for five days/week. At 2,000 mg/kg, 1/10 males and 2/10 females died before the end of the study; 1/10 females in the 500 mg/kg group also died before study termination. Several other animals also died as a result of gavage error. Mean body weights were 10% lower than control for male mice and 2% lower than control for female mice for the 1,000 and 2,000 mg/kg groups. Clinical signs of rough hair coats and decreased activity were reported for the two highest dose levels.

Male rats were dosed by oral gavage with 0, 2, 5, 10, 30 or 75 mg/kg *d*-limonene 5 days/week for 13 weeks. Linear regression analyses indicated increased relative kidney and liver weights at 30 and 75 mg/kg. Histological examination showed changes in the kidney characterized by hyaline droplet formation, granular casts and multiple cortical changes. Exacerbation of hyaline droplet formation was reported at the earliest necropsy eight days after administration at the 10 mg/kg dose level.

In a two-year NTP bioassay, male and female F344/N rats were dosed with 0, 75 or 150 mg/kg or 0, 300 or 600 mg/kg *d*-limonene for five days/week. Mean body weights for

the 150 mg/kg male rats were generally 4-7% lower than vehicle controls from week 2 to study termination. Mean body weights of the 600 mg/kg females were generally 4-7% lower than vehicle controls from week 28 to study termination. No treatment-related clinical signs were reported for the duration of the study. Survival of the 150 mg/kg male group was significantly greater than that of the vehicle alone after week 81. Survival of the 600 mg/kg female group was significantly lower than that of the vehicle controls after week 39. In the male rat kidneys, a dose-related increase was observed in the incidence of mineralization and epithelial hyperplasia. A dose-related increase in the severity of spontaneous nephropathy was reported in the treated male rats. Increased incidences in tubular cell hyperplasia and neoplasia were also reported in dosed male rats. Tubular cell adenoma incidence in 150 mg/kg male rats and tubular cell adenoma or tubular cell carcinomas (combined) in dosed male rats were significantly greater than vehicle controls. There was no evidence of carcinogenic activity of *d*-limonene for female rats receiving 300 or 600 mg/kg. The NOAEL for male rats (excluding the kidney effects) is 150 mg/kg/day (see below on the relevance of the male rat kidney effects for human risk assessment). The NOAEL for female rats is 300 mg/kg/day based on low survival in the 600 mg/kg dose group.

In a NTP two-year bioassay, male and female $B6C3F_1$ mice were dosed by oral gavage with 0, 250, or 500 mg/kg or 0, 500 or 1,000 mg/kg *d*-limonene, respectively, five days a week. Mean body weights for the 1,000 mg/kg female mice administered 1,000 mg/kg were generally 5-15% lower than vehicle controls from week 28 to study termination. No treatment related clinical signs were reported for the duration of the study. Survival of the 250 mg/kg male group was significantly lower than that of the vehicle controls by study termination. In the 500 mg/kg males, livers exhibited presence of cells with abnormal numbers of nuclei and cytomegaly. There was no evidence of carcinogenic activity of *d*-limonene for male or female $B6C3F_1$ mice at the dose levels tested. The NOAEL for male mice is 250 mg/kg/day based on liver effects at 500 mg/kg/day. Although there was reduced survival in the 250 mg/kg male mice, NTP did not considered this to be dose-related. The NOAEL for female mice is considered to be 500 mg/kg/day based on decreased survival and lower body weights (5 - 15%) in the 1,000 mg/kg dose group.

The kidney changes seen in male rats administered limonene have been well characterized, and are known to be specific to the male rat and of no significance in human risk assessment.

Genotoxicity

Given the structural similarity between the members of this chemical category, the substances in this category exhibit low genotoxic potential *in vitro.*

Mutagenicity/genotoxicity testing has been performed on three members of this chemical category, including a complete battery of *in vitro* genotoxicity tests using limonene. No evidence of mutagenicity was observed when limonene was incubated with *Salmonella*

typhimurium strains TA98, TA100, TA102, TA1535, TA1537, and TA1538 with and without S-9 metabolic activation at concentrations up to and including 150,000 μg/plate. Limonene did not induce chromosomal aberrations when incubated with Chinese hamster ovary cells at a concentration of 50-500 μg/ml, nor did it induce sister chromatid exchanges in Chinese hamster ovary cells at concentrations of 16.2-162 μg/ml. In a mouse lymphoma forward mutation assay, limonene was negative in L5178Y cells with and without S-9 metabolic activation up to a maximum concentration of 100 μg/ml. When incubated with Syrian hamster embryo cells up to 100 μg/ml or 3 mM, limonene did not induce statistically significant cell transformation. The effects of limonene on gap junction intercellular communications were also tested at concentrations up to 1 mM in Syrian hamster embryo cells, and showed no effects.

In an *in vitro* chromosome aberration test with human lymphocytes, myrcene did not induce chromosomal aberrations at concentrations up to 1,000 μg/ml with and without metabolic activation. When incubated with Chinese hamster ovary cells in a V79- HPRT Gene Mutation Assay, myrcene was not mutagenic with or without metabolic activation. In sister chromatid exchange (SCE) tests with human lymphocytes, myrcene did not induce sister chromatid exchanges at concentrations up to 1,000 μg/ml with or without metabolic activation. Additionally, there was no evidence of genotoxicity when myrcene was incubated with V79 and hepatic tumor (HPT) Chinese hamster cells at concentrations up to 500 μg/ml in SCE assays. In fact, myrcene reduced the SCE inducing effect of S-9 mix activated cyclophosphamide in human lymphocytes and Chinese hamster ovary (CHO) cells, and aflatoxin B1 in V79 and HTC Chinese hamster cells in a dose dependent manner.

No evidence of mutagenicity was observed when sweet orange peel oil was incubated with *Salmonella typhimurium* strains TA98, TA100, TA1535, TA1537, and TA1538 with and without S-9 metabolic activation at concentrations up to 5000 μg/plate. In a mouse lymphoma forward mutation assay, sweet orange peel oil was positive in L5178Y cells with and without S-9 metabolic activation up to a maximum concentration of 75 μg/ml but only at highly toxic concentrations. The authors noted that that positive results in this assay may be associated with changes in physiologic culture conditions (pH and osmolality). Negative results were obtained with sweet orange peel oil in the Rec DNA repair assay using *Bacillus subtilis* strains H17 and M45.

In eighteen separate *in vitro* tests on the mutagenicity and genotoxicity of limonene, myrcene, and sweet orange peel oil; the majority was negative, with the exception of the mouse lymphoma assay using sweet orange peel oil. This result is questionable given the culture conditions present and the negative results of the mouse lymphoma assay using limonene since limonene is the majority (greater than 90%) constituent of sweet orange peel oil.

Two *in vivo* genotoxicity assays are available for two substances in this chemical category. In an *in vivo* mammalian spot test, no evidence of mutagenicity was reported when mouse embryos were treated *in utero* with 215 mg/kg/day limonene on days 10 -11 of gestation.

In an *in vivo* cytogenetic bone marrow assay, *beta*-myrcene (100, 500 or 1,000 mg/kg) was orally administered *via* gavage to up to male and female Wistar rats. A dose- related increase in the mitotic index in bone marrow cells was reported for rats administered the test substance. The authors commented that this might be an interaction between *beta*-myrcene, which is known to induce CYP-450 enzymes, and colchicine, which arrests cell division at metaphase. *beta*-Myrcene may have increased the bioavailability of colchicine leading to the increase in mitotic index observed in the experiment. No significant increases in chromosomal aberrations were reported in the treated animals at either 24 or 48 hours. The authors concluded that given the results, *beta*-myrcene was not clastogenic to the rat when orally administered at dose levels up to 1,000 mg/kg. Based on the results of this *in vivo* genotoxicity assay and the numerous *in vitro* genotoxicity assays, it is unlikely that any of these materials would exhibit a significant genotoxic potential *in vivo*.

Reproductive Toxicity

Selected repeat dose toxicity studies were included in this toxicity profile. For summaries on all conducted studies, see the U.S. HPVIS.

beta-Myrcene was administered *via* gavage to female Wistar rats at dose levels of 250, 500, 1,000 and 1,500 mg/kg of *beta*-myrcene from the 15th day of gestation until weaning of the offspring which was day 21 postnatal. Fertility was impaired in female offspring exposed to 1,000 or 1,500 mg/kg *beta*-myrcene.

In a one-generation reproductive toxicity study, male and female Wistar rats were dosed by oral gavage with 0, 100, 300 or 500 mg/kg *beta*-myrcene. The exposure period was 91 days prior to and during the mating period for the males and 21 days prior to and during the mating period for females, pregnancy, and lactation until 21 days post parturition. Neither deaths nor signs of toxicity were reported in male rats at any dose level. No statistically significant differences in body weight gain were reported between control and test animals. A slight increase in liver and kidney weights was reported for treated male (highest dose only) and female rats. No morphological alterations of the liver or testis tissue were revealed upon microscopic examination. No effects were reported on the number of spermatids in the testis or on the number of spermatozoa in the cauda epididymis. No adverse effects on body weight gain and no other signs of toxicity were observed in treated female rats during the pre-mating or mating periods. No treatment related effects were reported on fertility as measured by the mating index and pregnancy index upon comparison to controls. At the highest dose level, a slight increase in the resorption rate and a parallel decrease in the ratio of live fetuses per implantation site were reported. Increases in the occurrence of fetal skeleton abnormalities between control and treated groups were reported at the 500 mg/kg level. No adverse effects were reported on duration of pregnancy, labor, pup mortality, and maternal or offspring weight changes. Slight delays in incisor eruption (300 mg/kg) and eye opening (100, 300 mg/kg) were reported but were not dose-related. The authors attributed the increase in skeletal

abnormalities at the highest dose level tested to known strain-specific anomalies including increases of dislocated sternums, and lumbar extra ribs. The authors concluded that the NOAEL for toxic effects on fertility and general reproductive performance *via* the oral route was 300 mg /kg for *beta*-myrcene.

Female rats were dosed by oral gavage with 0, 375, 750 or 1,500 mg/kg sweet orange peel for seven days prior to and through cohabitation, gestation, delivery and a four day lactation period. No deaths occurred at any dose level. Statistically significant numbers of rats from all three dose groups experienced excess salvation during the pre-mating and gestation periods, and during the lactation period for high-dose animals. The dosed rats had decreased weight gains compared to the control rats during the seven day premating period. Absolute and relative maternal food consumption was significantly decreased for the 750 and 1,500 mg/kg dose groups during the seven day premating period. No treatment related effect on mating performance or fertility was reported at any dose level. A significant increase in stillbirths and pup deaths was reported for the highest dose group compared to the control group (see next section for developmental effects).

Given the results of three reproductive toxicity assays using sweet orange peel oil predominantly composed of *d*-limonene and *beta*-myrcene, it may be concluded that the substances within this chemical category exhibit low reproductive toxicity potential.

Developmental Toxicity

Pregnant female Wistar rats were dosed by oral gavage with 0, 591 or 2,869 mg/kg *d*-limonene on days 9-15 of gestation. At the highest dose level, increases in maternal mortality and decreases in maternal and fetal body weights were reported. Additionally at the highest dose level, delayed ossification of fetal metacarpal bones and proximal phalanx and decreased weights of the thymus, spleen, and ovaries were reported. The NOAEL for both maternal and offspring toxicity was reported to be 591 mg/kg.

Pregnant Japanese white rabbits were administered 0, 250, 500 or 1,000 mg/kg *d*-limonene on days 6 to 18 of gestation. Increased maternal mortality was reported at the highest dose level. Significant decreases in maternal body weight gain and food consumption were temporarily observed at the 500 and 1,000 mg/kg dose levels. No treatment related effects were reported for the offspring. The NOAEL for maternal toxicity was reported to be 250 mg/kg/day. The NOAEL for offspring toxicity was reported to be greater than 1,000 mg/kg/day.

Pregnant ICR mice were administered 0, 591 or 2,363 mg/kg *d*-limonene on days 7 to 12 of gestation. Significant decreases in body weight gain were reported for pregnant ICR mice administered the highest dose level of *d*-limonene. In the offspring, increased incidence of fused ribs compared to that of the controls, delayed ossification of some bones and decreased body weight gain were reported at the highest dose level tested. The NOAEL for both maternal and offspring toxicity was reported to be 591 mg/kg/day.

Pregnant Wistar rats were administered 0, 250, 500 or 1,200 mg/kg *beta*-myrcene on gestational days 6-15. The vehicle was corn oil. Decreased maternal weight gain was reported at the 1,200 mg/kg dose. Increased fetal skeletal malformations were reported at the 1,200 mg/kg dose level. The NOAEL for both maternal and offspring toxicity was reported to be 500 mg/kg/day.

beta-Myrcene was administered *via* gavage to female Wistar rats at dose levels of 250, 500, 1,000 or 1,500 mg/kg from pregnancy day 15 until weaning of the offspring, which was day 21 postnatal. Mortality, weight gain and post-natal development were evaluated. Reproductive capacity was assessed in the exposed offspring upon reaching maturity (120 days). No adverse effects were noted in the offspring at the lowest dose level tested. Decreased body weight, increased perinatal mortality, and delayed developmental landmarks were noted at the 500, 1000 and 1500 mg/kg dose levels. Fertility was impaired in female offspring exposed to the two highest doses of *beta*-myrcene. The NOAEL for peri- and post-natal development was set at 250 mg/kg/day.

Female rats were dosed by oral gavage with 0, 375, 750 or 1,500 mg/kg sweet orange peel for seven days prior to and through cohabitation, gestation, delivery and a four day lactation period. No deaths occurred at any dose level. Statistically significant numbers of rats from all three dose groups experienced excess salvation during the premating and gestation periods, and during the lactation period for high-dose animals. The dosed rats had decreased weight gains compared to the control rats during the seven-day premating period. Absolute and relative maternal food consumption was significantly decreased for the 750 and 1500 mg/kg/day dose groups during the seven day premating period. No treatment related effects were reported on maternal body weight, changes in body weight, and absolute and relative feed consumption during the lactation period. No treatment related effect on mating performance or fertility was reported at any dose level. A significant increase in stillbirths and pup deaths was reported for the highest dose group compared to the control group. The treatment with sweet orange oil had no effect on the incidence of malformations or gross lesions in the pups. The NOAEL for this study was reported to be less than 375 mg/kg/day for maternal toxicity and 750 mg/kg/day for offspring development.

Given the results of six developmental toxicity assays using limonene, sweet orange oil and *beta*-myrcene, it may be concluded that the substances within this chemical category exhibit low developmental toxicity potential.

Key Study/Critical Effect for Screening Criteria

The toxicity data on d-limonene will be used as read-across to CAS No. 68956-56-9 and 68647-72-3. The kidney changes seen in male rats administered limonene have been well characterized, and are known to be specific to the male rat and of no significance in human risk assessment. Thus, the male rat kidney effects will not be considered in the determining the critical effect for a drinking water guideline value.

In the NTP two-year rat bioassay, the NOAELs for male and female rats were 150 and 300 mg/kg/day, respectively. In the NTP two-year mouse bioassay, the NOAELs for male and female mice were 250 and 500 mg/kg/day, respectively.

The lowest NOAEL is 150 mg/kg/day for male rats in the NTP 2-year bioassay based on liver effects. Adjusting for 5 days/week to 7 days/week, results in a NOAEL for continuous exposure of 107 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 107/100 = 1.1 mg/kg/day

Drinking water guidance value = 3.8 ppm

Toxicity Profile

Hydrochloric acid
(CAS No. 7647-01-0)

Hydrochloric acid has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Hydrochloric acid (HCl) or hydrogen chloride is readily dissociated in water into hydrated protons and chloride ion.

Acute Toxicity

The oral LD_{50} value of hydrogen chloride is reported to be 238 to 277 mg/kg for female rats (Hoechst AG, 1966), and 900 mg/kg for rabbits (Loewy and Munzer, 1923). The lethal dose by dermal exposure is >5,010 mg/kg for rabbits (Monsanto, 1976). The LC_{50} values for HCl are reported to be 23.7 - 60.9 mg/L/5min, 5.7- 7.0 mg/L/30min and 4.2 4.7 mg/L/60min for rats; and 20.9 mg/L/5min, 3.9 mg/L/30min and 1.7 mg/L/60min for mice (Darmer *et al.*, 1974; Hartzell *et al.*, 1990; MacEwean *et al.*, 1974).

Irritation

Concentrations >3.3% cause skin irritation, and concentrations >17% cause corrosion in animal studies (OECD, 2002a,b). An aqueous solution (4%) of hydrogen chloride was slightly irritating (Agner and Serup, 1988), and a 10% solution was determined to be 'Irritating to skin' for the EU Dangerous Preparations Directive, in human volunteer experiments (York *et al.*, 1996).

0.1 mL of 10% aqueous solution of HCl was highly irritating to the eyes of rabbits (Jacobs, 1992); 0.03 mL or more of 5% HCl was corrosive to the eyes of rabbits (Griffith *et al.*, 1980); 0.1 mL of a 3.3% aqueous solution of HCL was slightly irritating the eyes of rabbits (Hoechst AG, 1966); and 0.1 mL of a 0.33% aqueous solution of HCl was not irritating to the eyes of rabbits. (Hoechst AG, 1966).

Sensitization

Hydrogen chloride is not a skin sensitizer to guinea pigs and humans (Gad *et al.*, 1986).

Repeated Dose Toxicity

Rats were fed diets containing 280 to 1,250 mmol/kg hydrochloric acid (10.2 to 45.6 mg/kg) for 7-12 weeks. There was increased water intake in all treated groups. All

animals fed diet containing 937 mmol/kg and above for 9 weeks, and half of the animals fed diet containing 900 mmol/kg for 12 weeks died. Also at doses ≥937 mmol/kg, there was decreased body weight, food consumption, blood pH, femur length, rate of ash in bone (Upotn and L'Estrange, 1977). In another study with rats, hydrochloric acid was administered via drinking water at pH 2-3 (study duration not provided). Decreased protein levels in urine and decreased urine volumes were observed in the treatment groups (Clausing and Gottschalk, 1989).

Genotoxicity

While consistent negative results have been obtained in the bacterial systems, positive results have been obtained in the non-bacterial systems (OECD, 2002a,b). The positive results were observed at high concentrations, but they were considered to be artifacts due to the low pH. Positive results were obtained in a sex-linked recessive lethal study with *D. melanogaster*; only one dose level was tested (Stumm-Tegethoff, 1966) There are no mammalian studies on *in vivo* mutagenicity with hydrogen chloride

Carcinogenicity (Oral Studies only)

A ten-month study has been conducted using mice (Dyer *et al.*, 1946). Because the methods such as strain used, duration and dose of administration, presence of co-administration substance, were not appropriate, it cannot be used for the assessment of carcinogenicity of hydrochloric acid.

Reproductive Toxicity

No reliable studies were identified by the oral route.

Developmental Toxicity

No reliable studies were identified by the oral route.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for pH may apply to hydrochloric acid.

Toxicity Profile

Monoethanolamine borate
(CAS No. 26038-87-9)

The toxicity profile includes toxicity data on boric acid, reaction products with ethanolamine and triethanolamine (CAS No. 68512-53-8), which is structurally similar to monoethanolamine borate.

Acute Toxicity

The acute oral LD_{50} in rats is >2,000 mg/kg, and the acute dermal LD_{50} of CAS 68512-53-8 in rats is >2,000 mg/kg.

Irritation

Monoethanolamine borate was slightly irritating and was not considered to be a skin irritant when tested on the skin of rabbits. Monoethanolamine (MEA) Polyborate 1:1 and MEA Polyborate 1:3 were tested for eye irritancy using the Bovine Corneal Opacity and Permeability test (BCOP test). Minimal to no ocular irritation was observed in both studies.

Sensitization

CAS No. 68512-53-8 was not a skin sensitizer to guinea pigs using the Buehler method.

Repeated Dose Toxicity

Groups of male and female rats received CAS No. 68512-53-8 by oral gavage at dose levels of 0, 62.5, 250 or 1,000 mg/kg body weight per day for a period of 28 days. No deaths occurred throughout the study. Behavior, state of health, body weight development and food consumption, were not affected by administration of the test substance. No treatment-related clinical signs were observed in all animals. No changes of the oral mucosa or impairment of dental growth was observed in all study groups. There were no substance related adverse findings either in hematological examinations, clinical chemistry or urine analyses throughout the study period. As a non-adverse finding, the test substance induced slightly lower total bilirubin, cholesterol and triglycerides in high dose group rats (1,000 mg/kg body weight) and possibly marginally lower hemoglobin and hematocrit content when compared to the controls at the end of the study period. These changes were at the lower range of the historical control data for this rat strain and age and hence, not considered to be of toxicological significance. The test

substance did not influence any of the neurotoxicological parameters. No test article related changes in organ weights were observed. Necropsy at terminal sacrifice revealed no gross pathology findings in the animals of all experimental groups. All microscopic findings sporadically observed in different organs of single animals were interpreted as not compound related. The NOAEL for this study is 1,000 mg/kg/day.

Genotoxicity

In an *in vitro* chromosomal aberration test using cultured peripheral human lymphocytes, MEA Polyborate 1:1 showed a clastogenic response in experiments where the pH of the treated cultures was above the pH of the solvent control. The clastogenicity was only observed in the first cytogenetic assay. Due to fact that the adjustment of the pH of the cultures treated with MEA Polyborate 1:1 did not show a clastogenic response in the third cytogenetic assay, it has to be assumed that the high pH is responsible for the detected clastogenic activity.

In an *in vitro* chromosomal aberration test using cultured peripheral human lymphocytes, MEA Polyborate 1:3 did not induce a statistically significant or biologically relevant increase in the number of cells with chromosome aberrations in the absence and presence of S9-mix, in either of the two independently repeated experiments. CAS No. 68512-53-8 did not induce gene mutations in an *in vitro* HPRT-test with V79 Chinese hamster lung fibroblast cells, either in the presence or in the absence of metabolic activation.

Carcinogenicity

No data are available.

Reproductive Toxicity

No data are available.

Developmental Toxicity

No data are available.

Key Study/Critical Effect for Screening Criteria

A 28-day oral toxicity study conducted was conducted in rats with CAS No. 68512-53-8 (Boric acid, reaction products with ethanolamine and triethanolamine). The NOAEL for this study is 1,000 mg/kg/day. Data from CAS No. 68512-53-8 is being used as read-across to monoethanolamine borate.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subacute to chronic)

Oral RfD = 1000/1000 = 1 mg/kg/day

Drinking water guideline: 3.5 ppm

Reference

ECHA REACH database: http://apps.echa.europa.eu/registered/registered-sub.aspx

Toxicity Profile

PEG Oleate Ester
[Poly(oxy-1,2-ethanediyl), .alpha.-hydro-.omega.-hydroxy-, (9Z)-9-octadecenoate]
(CAS No. 56449-46-8)

Ethoxylated fatty acids are also called PEG fatty acid esters because the substance is a PEG chain linked to a fatty acid via an ester linkage. Data were located on the PEG stearate, PEG laurate, and PEG castor oil; these substances will be used as a surrogates for this substance.

Acute Toxicity

The acute oral LD_{50} of PEG stearates (50% preparations) were >10,000 mg/kg in rats, and the acute dermal LD_{50} of PEG stearate (15% preparation) was >10,000 ml/kg in rabbits.

Irritation

PEG stearates (100%) were mildly irritating the skin of rabbits, and non-irritating to human skin. PEG stearates (100%) was minimally irritating to the eyes of rabbits. PEG castor oils (100%) was considered non-irritating to the eyes of rabbits.

Sensitization

Clinical studies on the PEG stearates indicate that these ingredients are neither irritants nor sensitizers at concentrations of ≤25%.

Repeated Dose Toxicity

PEG-8 stearate at 5% in the diet did not produce any treatment-related effects in rabbits after 19 weeks, or any treatment-related effects at 4% after 4 months.

In a two-year dietary study, PEG-8 stearate at 4% produced no treatment-related effects over three generations. Likewise, PEG-100 at 2% did not produce any treatment-related effects over three generations in a two-year dietary study.

In a two-year dietary study, male and female rats (12/sex/dose) were given 0, 2, 5, 10, and 25% PEG-20 laurate in feed, At 25%, growth reduction occurred in the male rats, three rats had gastric mucosa hyperplasia, hepatic cysts in five rats, and cecal enlargement in 17 animals. At 10%, there were hepatic cysts in four rats and cecal

enlargement in four animals. At 5%, there was one hepatic cyst and cecal enlargement in three animals. At 2%, there was one hepatic cyst, and cecal enlargement in two animals (Fitzhugh et al., 1960).

Genotoxicity

There is no indication of a genotoxic effect of PEG fatty acids.

Carcinogenicity

No carcinogenicity studies could be located for PEG fatty acids.

Reproductive/Developmental Toxicity

Multi-generation studies with PEG- 40 stearates showed no adverse effects on reproduction and development. There was no evidence of developmental toxicity seen in mice and rat feeding studies with PEG-35 castor oil.

Key Study/Critical Effect for Screening Criteria

Liver cysts and cecal enlargement were seen in all tested rats given PEG-20 laurate in feed for two years. It cannot determined whether the lowest concentration tested (2%) is a LOAEL or a NOAEL. Thus, for the purposes of this risk assessment, the 2% concentration in this study will be considered a LOAEL.

NOAEL (mg/kg/day) = 20,000 ppm * 0.05 = 1,000 mg/kg/day

Where 0.05 is the fraction of body weight that is consumed per day as food for the rat (U.S. EPA).

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (LOAEL to NOAEL)

Oral RfD = 1,000/1,000 = 1 mg/kg/day

Drinking water guidance value = 3.5 ppm

Toxicity Profile

Sodium hydroxide
(CAS No. 1310-73-2)

Sodium hydroxide (NaOH) has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Sodium hydroxide (NaOH) is present in the environment as sodium (Na^+) and hydroxyl ions (OH^-). Sodium is a normal constituent of the blood and an excess is excreted in the urine. A significant amount of sodium is taken up via the food because the normal uptake of sodium via food is 3.1-6.0 g per day according to Fodor *et al.* (1999). Exposure to NaOH could potentially increase the pH of the blood. However, the pH of the blood is regulated between narrow ranges to maintain homeostasis (pH of 7.4 to 7.5) by urinary excretion of bicarbonate and via exhalation of carbon dioxide.

Acute Toxicity

An oral LD_{50} of a 1-10% solution of NaOH in rabbits was reported to be 325 mg/kg (expressed as 100% NaOH). Mortality was also observed when 1% NaOH was dosed, but in this case, the applied volume was relatively high (24 mL per kg body weight).

Irritation

A NaOH solution of 8% can be considered corrosive based on animal data. Human data indicate that concentrations of 0.5 to 4% were irritating. In two different studies a concentration of 0.5% was irritating for only 55 and 61% of the volunteers, respectively. Thus, it is assumed that a concentration, which is slightly lower than 0.5%, is the non-irritating concentration.

The available animal data on eye irritation showed that the non-irritant level was 0.2-1.0 %, while the corrosive concentration was 1.2 % or >2%.

Sensitization

Male volunteers were exposed on the back to sodium hydroxide concentrations of 0.063 – 1.0% (induction). After 7 days the volunteers were challenged to a concentration of 0.125%. The irritant response correlated well with the concentration of NaOH, but an increased response was not observed when the previously patch tested sites were re-challenged. Based on this study sodium hydroxide has no skin sensitization potential.

Repeated Dose Toxicity

No animal data are available on repeated dose toxicity studies by oral, dermal, inhalation or by other routes for NaOH. It is not useful to study the repeated dose toxicity of hydroxide via an oral study because at high concentrations the substance is corrosive or irritating, while at low concentrations the hydroxide will be neutralized in the stomach by gastric juice, which has a very low pH.

Genotoxicity

Both the *in vitro* and the *in vivo* genotoxicity tests are negative.

Carcinogenicity

No carcinogenicity studies on sodium hydroxide were identified.

Reproductive Toxicity

No valid studies were identified regarding toxicity to reproduction in animals after oral, dermal or inhalation exposure to NaOH. It is not useful to study the reproduction/developmental toxicity of hydroxide via an oral study because at high concentrations the substance is corrosive or irritating, while at low concentrations the hydroxide will be neutralized in the stomach by gastric juice, which has a very low pH.

Developmental Toxicity

No valid studies were identified regarding developmental toxicity in animals after oral, dermal or inhalation exposure to NaOH. It is not useful to study the reproduction/developmental toxicity of hydroxide via an oral study because at high concentrations the substance is corrosive or irritating, while at low concentrations the hydroxide will be neutralized in the stomach by gastric juice, which has a very low pH.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for pH may apply to sodium hydroxide.

Reference

OECD (2002). IUCLID Data Set for Sodium hydroxide (CAS No. 1310-73-2), UNEP Publications.

OECD (2002). Screening Information Dataset (SIDS) Initial Assessment Report for Sodium hydroxide (CAS No. 1310-73-2), UNEP Publications.

Toxicity Profile

Sodium sulfate
(CAS No. 7757-82-6)

Sodium sulfate has been reviewed in the OECD-SIDS program (OECD, 2005a,b).

Acute Toxicity

The acute toxicity (LD_{50}) of sodium sulfate has not been reliably established. Human data indicate a very low acute toxicity of sodium sulfate. High oral doses of sodium sulfate, from 300 mg/kg up to 20 grams for an adult, are well tolerated, except from (intentionally) causing severe diarrhea. There are no data on acute dermal toxicity.

Irritation

Sodium sulfate is not irritating to the skin and slightly irritating to the eyes. Respiratory irritation has never been reported.

Sensitization

Sodium sulfate is unlikely to be a skin or respiratory sensitizer based on wide practical experience with sodium sulfate, in combination with the natural occurrence of sulfate in the body.

Repeated Dose Toxicity

Valid oral repeated dose toxicity studies with 21, 28 and 35 day studies in hens and pigs are available. Toxicity was confined to changes in bodyweight, water and feed intake and diarrhea These changes occurred only at very high doses of sodium sulfate. The available data do not allow for the derivation of a NOAEL. Based on available consumer data, a daily dose of around 25 mg/kg/day is well tolerated by humans.

Genotoxicity

Sodium sulfate was not mutagenic in an Ames test.

Carcinogenicity

There is no valid oral carcinogenicity study. Limited data from experimental studies

support the notion that a substance that is abundantly present in and essential to the body is unlikely to be carcinogenic.

Reproductive/Developmental Toxicity

Limited data of poor validity did not provide an indication of toxicity to reproduction.

Key Study/Critical Effect for Screening Criteria

Exposure to sodium sulfate occurs via drinking water and through naturally occurring amounts in foodstuffs. In drinking water (wells) concentrations up to 2 g/L were measured in the U.S. The taste threshold for sodium sulfate is 250 – 900 mg/L. The maximum acceptable concentration for drinking water is 200 – 500 mg/L sulfate and is based on taste.

No data on the sulfate content of foodstuffs were found; however, according to WHO, sulfates are used as additives in the food industry and the estimated average daily intake of sulfate in food in the U.S. is 453 mg/person, based on data on food consumption and reported usage of sulfates as additives. An Acceptable Daily Intake for sodium sulfate has not been established.

The Australian drinking water guideline values for sodium and sulfate may apply to sodium sulfate.

OECD (2005). IUCLID Data Set for Sodium sulfate (CAS No. 7757-82-6), UNEP Publications.

OECD (2005). Screening Information Dataset (SIDS) Initial Assessment Report for Sodium sulfate (CAS No. 7757-82-6), UNEP Publications.

Toxicity Profile

Sodium sulfite
CAS No. 7757-83-7)

Sodium sulfite has been reviewed in the OECD-SIDS program (OECD, 2008a,b).

Sodium sulfite is completely dissociated in aqueous media into 2 Na^+ and sulfite anion (SO_3^{2-}). Sodium sulfite is a salt of sulfurous acid (H_2SO_3). In aqueous solutions, sulfurous acid dissociates, the dissociation constants are pK_{a1} of 1.8 and pK_{a2} of 7.0 at 25°C. At neutral pH, a mixture of 50% sulfite (SO_3^{2-}) and 50% bisulfite (HSO_3^{2-}) is present. At concentrations above 1M, bisulfite anions will dimerize with the elimination of water to form metabisulfite ($S_2O_5^{2-}$). At low concentrations, metabisulfite will hydrolyze to form bisulfite.

In surface waters, sulfite is oxidized to sulfate either catalytically by air oxygen or by microbial action. The presence of cations like iron, copper or manganese in the environment accelerates the oxidation rate significantly.

Sodium sulfite is rapidly absorbed from the gastro-intestinal tract. Sulfate is the main metabolite formed by the action of sulfite oxidase in many tissues. Tissue accumulation of sulfite-derived S is highest in stomach, skin and hair, intestine and kidney. Excretion is rapid, mainly in the urine.

Acute Toxicity

The oral LD_{50} values are $\geq$ 3,560 mg/kg in rats and 820 – 920 mg/kg in mice. No dermal LD_{50} values or acute LC_{50} values are available.

Irritation

Sodium sulfite was not irritating to the skin or eyes of rabbits.

Sensitization

No dermal sensitization studies in animals are available. In humans, some cases of sensitization from topical contact with sodium sulfite have been described. Only 1.4% of a population of 1762 eczema patients showed a positive reaction to sodium sulfite in patch tests.

Repeated Dose Toxicity

In a 90-day feeding study, a NOAEL for male rats of 2% in diet corresponding to 1,670 mg/kg/day was found. The LOAEL was 4% in diet based on decreased body weight gain and increased relative weights of testis and brain. In female rats, the highest tested dose of 4% in diet was the NOAEL corresponding to 3,070 mg/kg/day.

A two-year rat feeding of sodium metabisulfite ($Na_2S_2O_5$). The NOAEL was 0.5%, which is equivalent to a dose of 144 mg/kg/day calculated as sodium sulfite. The LOAEL for local effects (forestomach and glandular stomach hyperplasia or inflammation) corresponded to 1.0% in diet, which is equivalent to 300 mg/kg/day calculated as sodium sulfite. The NOAEL for systemic effects corresponded to the highest dose of 2% in diet (equivalent to 625 mg/kg/day calculated as sodium sulfite).

Genotoxicity

Sodium sulfite is not genotoxic based on the available studies that have been conducted *in vitro* and *in vivo*.

In vitro, sodium sulfite gave no indication of mutagenic or clastogenic activity up to cytotoxic concentrations both in the absence and presence of metabolic activation systems when tested in Ames tests/*Salmonella typhimurium* reversion assays, in gene mutation tests with *Saccharomyces cerevisiae* and in mammalian V79 cells (without metabolic activation), in a DNA damage and repair assay with *Escherichia coli*, as well as in a chromosomal aberration test with CHL cells (without metabolic activation).

There are no *in vivo* tests with application of pure sodium sulfite. Several genotoxicity studies *in vivo* with sulfites other than sodium sulfite were negative. The negative findings in whole animals are regarded as consistent with the high reactivity of sulfite e.g. with proteins and its rapid inactivation in mammals due to metabolism. However, in contrast to the consistent negative findings in earlier studies, recent investigations of a single working group demonstrated dose-dependent increases of micronuclei in bone marrow and DNA damage in tissues of mice after intraperitoneal injection of a mixture of sodium sulfite and sodium bisulfite. No parallel investigations were performed with the pure compounds as controls.

Carcinogenicity

There are no carcinogenicity studies available with administration of sodium sulfite.

Male and female Wistar rats exposed to sodium metabisulfite ($Na_2S_2O_5$) given in the diet with 0.125, 0.25, 0.5, 1.0 and 2.0% and supplemented with thiamine due to its breakdown by sulfite in the diet) for 104 weeks. The number of lymphoreticular pulmonary tumors in males decreased with increasing levels of sulfite. The incidence of thyroid and

pituitary tumors in control males was exceptionally low, whereas those noted in the various test groups represented numbers normally found in the strain of Wistar rats used. All other neoplasms occurred in a sporadic manner with no apparent relationship between number, location or type of tumors and the treatment.

Male and female mice were given 0, 1 or 2% potassium metabisulfite in drinking water for 104 weeks. There was no increased incidence of tumors in the treated mice compared to controls.

Reproductive Toxicity

There are no reproductive toxicity studies with sodium sulfite investigating effects on male or female fertility.

In a three-generation study with sodium metabisulfite (Na2S2, there was no suggestive evidence of reproductive toxicity or impairment of fertility in rats that received up to 2% in the diet. No effects on gonads were seen histologically. This NOAEL for reproductive toxicity would be equivalent to a dose of 625 mg/kg bw/day calculated as sodium sulfite, which is higher than the NOAEL for chronic toxicity of 0.5% in the diet (based on local irritation of the stomach), being equivalent to a dose of 144 mg/kg bw/day calculated as sodium sulfite.

In a long-term (see repeat dose toxicity section for results) and three-generation study, rats were treated with 0, 0.125, 0.25, 0.5, 1.0 and 2.0% of sodium metabisulfite (corresponding to 0, 32, 70, 144, 300 and 625 mg/kg/day as Na_2SO_3 equivalents) in a supplemented diet with thiamine, since sulfites are known to break down thiamine in the diet. F_0- and F_1-generation were exposed for 104 weeks, and the F_2-generation for 30 weeks. The F_0-generation was mated at week 21 of treatment. Half of the animals were mated again at week 34. Animals from the first litter were selected at weaning to become the F_{1a}-generation being mated at weeks 12 and 30 to produce F_{2a}- and F_{2b}-generations. Animals from the F_{2a} litters were mated to produce the F_{3a}- and F_{3b}-generations by pairing on weeks 14 and 22.

Body weight was not reduced in any treatment group in the F_0-generation. There was a marginal reduction in body weight in both sexes of the 2% group in the F_1- and F_2-generations. Results in successive generations showed no substantial treatment-related effects in terms of fertility, the number of animals/litter or the birth weight or mortality of the young. During lactation the body weight of the young in the 2% group was generally lower than the controls and the lower-dosed groups. This reduced body weight was probably not a true substance-related effect because it was transient and could be due to a higher initial body weight in the control groups. A reduction in the number of F_{2a}-generation offspring (F_{3a} pups) was observed in the 0.5, 1.0 and 2.0% dose groups, but it was not dose-dependent and did not occur in the F_{2b}-generation offspring (F_{3b} pups).

No pronounced effects were observed on reproductive performance in any generation and no effects on gonads were seen histologically. The NOAEL for reproduction toxicity was

the highest dose of 2% in the diet (625 mg/kg/day calculated as sodium sulfite). The NOAEL for chronic toxicity of the F_0-generation corresponding to 0.5% in the diet (144 mg/kg/day calculated as sodium sulfite). The LOAEL for local effects (irritation of the stomach) corresponded to 1.0% in diet (300 mg/kg/day calculated as sodium sulfite). The NOAEL for systemic effects corresponded to the highest dose of 2% (625 mg/kg/day calculated as sodium sulfite).

Developmental Toxicity

Pregnant female Wistar rats were given in their diet 0, 0.32, 0.63, 1.25, 2.5 or 5% sodium sulfite heptahydrate (ca. 0, 150, 300, 550, 1,050 or 1,650 mg/kg as sodium sulfite) on gestational days 8-20. Satellite groups of 4 rats received 0, 0.32 or 5% in the diet on the same days and were allowed to deliver and rear their litters to weaning. In dams, statistically significant decreased food consumption was seen at 150, 300 or 1650 mg sodium sulfite/kg and body weight gains were also significantly decreased at 1,650 mg/kg during the exposure period. In fetuses of all dosed animals, there was a decrease in fetal body weights without clear dose-response relationship. In the satellite groups there was no evidence of toxicity or growth retardation in dams or offspring during a 21-day lactation period. The observed fetal growth retardation was without clear dose-response relationship and there were also no adverse findings concerning this endpoint in the satellite groups allowed to deliver and rear their litters to weaning. Therefore, the relevance of this isolated effect is questionable and is not considered as adverse finding. There was no indication for teratogenic effects at all tested doses. The NOAEL for maternal toxicity is 1,050 mg/kg/day and the NOAEL for developmental effects is 1,650 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline values for sodium and sulfate may apply to sodium sulfate.

Reference

OECD (2008). IUCLID Data Set for Sodium sulfite (CAS No. 7757-83-7).

OECD (2008). Screening Information Dataset (SIDS) Initial Assessment Report for Sodium sulfite (CAS No. 7757-83-7).

Toxicity Profile

Sodium thiosulfate (CASRN 7772-98-7)

Thiosulfate is a metastable, moderately reducing oxyanion of sulfur. Chemical reactions (redox reactions) of thiosulfate generate chemical species of sulfur that differ in their oxidation state. The thiosulfate anion ($S_2O_3^{2-}$) is only stable in neutral or alkaline media. It is unstable in acid media. In aqueous media, thiosulfate irreversibly disproportionates to sulfide and sulfate. The chemistry of sulfur in soils (and in water) is complex because of its many oxidation states. The terminal, thermodynamically-favored reaction product of thiosulfate is sulfate, except in highly reduced soils.

Acute Toxicity

The acute oral LD_{50} of an aqueous solution of calcium thiosulfate is >2,000 mg/kg in female rats. For ammonium thiosulfate, the acute oral rat LD_{50} is 4,054 mg/kg in males, 3,500 mg/kg, and 3,824 mg/kg in combined sexes. The acute oral LD_{50} of potassium thiosulfate solution was estimated to be >5,000 mg/kg (for pure test item > 2,500 mg/kg) in the rat.

Irritation

No data were located.

Sensitization

Ammonium thiosulfate at concentrations of 10%, 25% and 50% (w/w) in aqua ad iniectabilia did not reveal any sensitising properties in the local lymph node assay.

Repeated Dose Toxicity

No data on sodium thiosulfate were located.

Genotoxicity

Ammonium thiosulfate was not mutagenic in the bacterial reverse mutation assay using *S. typhimurium* tester strains TA 98, TA 100, TA 1535 and TA 1537 and *Escherichia coli* strain WP2 *uvr*A in the presence and absence of metabolic activation system. Ammonium thiosulfate was negative in an *in vitro* chromosomal aberration assay using CHO cells. Ammonium thiosulfate was also negative in a mouse lymphoma cells.

Carcinogenicity

No data on sodium thiosulfate were located.

Reproductive Toxicity

No data on sodium thiosulfate were located.

Developmental Toxicity

The administration of up to 550 mg/kg sodium thiosulfate to pregnant mice for 10 consecutive days had no clearly discernible effect on nidation or on maternal or fetal survival. The number of abnormalities seen in either soft or skeletal tissues of the test groups did not differ from the number occurring spontaneously in the sham-treated controls. Thus, the NOAEL for maternal and developmental toxicity can be expected above the highest dose of 550 mg/kg.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline values for sodium and sulfate may apply to sodium thiosulfate.

Toxicity Profile

Sorbitan Monooelate
(CAS No. 1338-43-8)

Sorbitan fatty acid esters are non-ionic surfactant-active agents that typically find use as emulsifiers, stabilizers and thickeners in foods, cosmetics, medical products, lubricants and other applications (Andersen, 2002; Eisenhard, 1999). Sorbitan monooleate is approved by FDA as an indirect food additive.

The information in this toxicity profile was obtained from the U.S. EPA HPV Test Plan for Sorbitan Esters Category of the Aliphatic Esters Chemicals, November 26, 2003.

Metabolism

Metabolism of the sorbitan esters in animals has been reported to occur initially via enzymatic hydrolysis, leading to sorbitan and the corresponding natural fatty acids. Oral gavage studies in rats with radiolabelled sorbitan monostearate, which is structurally similar to sorbitan monooleate, have demonstrated that about 90% of the sorbitan monostearate dose was absorbed and hydrolyzed to stearic acid and sorbitan (Elder, 1985; Wick, 1953). The resulting sorbitan and fatty acid metabolites, in turn would be expected to be metabolized further (via fatty acid beta-oxidation or carbohydrate metabolic pathways) to either smaller and more polar water-soluble metabolites, which can be excreted in the urine or as carbon dioxide exhaled in the lungs.

Acute Toxicity

The acute oral LD_{50} for sorbitan monooleate in rats was reported to be > 39,800 mg/kg (Elder, 1985).

Irritation

No data were located.

Sensitization

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Oral feeding toxicity studies have been carried out in rats for 16 weeks with sorbitan

monooleate at dietary concentrations of 0, 2.5, 5 and 10% (Ingram *et al.*, 1978). The LOAEL was 2.5% dietary concentration (~1800 mg/kg/day) based on increased kidney weight findings that were considered significant in both male and female rats.

Sorbitan monooleate fed to rats at 5% concentrations in the diet for 2 years showed no adverse effects on growth, hematology, clinical chemistry, survival, organ size or histopathology (ACI, 1970). The NOAEL was reported to be 5% in the diet for sorbitan monooleate in this study.

Genotoxicity

No genotoxicity studies could be located for sorbitan monooleate; however, there are two studies conducted on the structurally similar substance sorbitan monostearate.

Sorbitan monostearate was not mutagenic to *Salmonella typhimurium* TA98 and TA100 in a Ames mutation assay in the presence or absence of metabolic activation (Inoue *et al.*, 1980). Sorbitan monostearate did not cause any chromosomal aberrations in the Syrian golden hamster embryo cell assay and did not show clastogenic activity Inoue *et al.*, 1980).

Reproductive/Developmental Toxicity

No studies could be located for sorbitan monooleate; however, there is one study conducted in the structurally similar substance sorbitan monostearate.

Sorbitan monostearate was administered in the diet at dose levels of 0, 5, 10, and 20% over a period of two years and over four generations of rats (Oser *et al.*, 1956a,b; Oser et al., 1957a,b). No effects were observed on growth, food efficiency, reproduction, lactation, metabolism, behavior, mortality, or in the gross and histopathological examination. At the 20% dose level in the diet, newborn mortality was not increased but there were slight effects on growth and impairment of lactation.

Key Study/Critical Effect for Screening Criteria

No treatment-related effects were noted in a two-year carcinogenicity study in which rat were fed sorbitan monooleate in the diet at concentrations up to 5% (50,000 ppm).

NOAEL (mg/kg/day) = 50,000 ppm * 0.05 = 2,500 mg/kg/day

Where 0.05 is the fraction of body weight that is consumed per day as food for the rat (U.S. EPA).

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 2,500/100 = 25 mg/kg/day

Drinking water guidance value = 87.5 ppm

Toxicity Profile

Terpenes and Terpenoids
Terpenes and Terpenoids, Sweet Orange Oil
(CAS No. 68647-72-3)

The chemical category designated terpenes and terpenoids are hydrocarbons that can include C_{10} isomeric monocyclic terpene hydrocarbons (*d*-limonene, *dl*-limonene, and terpinolene) and two C_{10} acyclic terpene hydrocarbons (*beta*-myrcene and dihydromyrcene).

Terpenes and terpenoids, sweet orange oil (CAS 68647-72-3) is composed of 91-95% d-limonene, 1-3% beta-myrcene, and 1-2% alpha-pinene.

Acute Toxicity

The oral and dermal LD_{50} values for limonene, myrcene, terpinolene, dihydromyrcene and sweet orange peel oil indicate a low order of both oral and dermal toxicity. All rabbit and rat dermal, and mouse and rat oral LD_{50} values are >4,000 mg/kg with the majority of values being >5,000 mg/kg.

Irritation

No data were located.

Sensitization

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Selected repeat dose toxicity studies were included in this toxicity profile. For summaries on all conducted studies, see the U.S. HPVIS.

Groups of ten Sprague Dawley rats of each sex were administered 0, 240, 600 or 1,500 mg/kg sweet orange oil in 1% methyl cellulose by gavage daily for 30 days. Observations included survival, clinical observations, body weights, food consumption, clinical pathology, gross pathology, organ weights and histopathology. No treatment related effects were reported for survival, clinical observations, body weights or food consumption. Decreases in glucose levels related to treatment were reported in the mid-dose females and high-dose males and females. Increases in serum albumin and total

serum protein were observed in all treated females and the high-dose males. Histopathology revealed treatment related lesions in the nonglandular stomach of the high-dose males and females and in the kidney of all treated male groups. Kidney weights were also increased in all of the treated male groups and in the high-dose female group. Liver weight increases related to treatment were reported for the high-dose females and all treated male groups. The authors concluded that the no-observed-effect-level (NOEL) under conditions of this study was less than 240 mg/kg/day for both male and female rats. The authors noted that the kidney changes observed in the male rat at all dose levels were expected given the known interaction between limonene and *alpha*-2-microglobulin. Limonene is the principal constituent of orange oil.

In a NTP 13-week study, male and female F344/N rats were dosed by oral gavage 0, 150, 300, 600, 1,200 or 2,400 mg/kg *d*-limonene in corn oil for 5 days/week. At 2,400 mg/kg, 9/10 female rats and 5/10 male rats (5/10) died within the first week of the study. The final mean body weights of male rats receiving the three highest doses (600, 1,200 or 2,400 mg/kg) were reported to be 6%, 12%, or 23% lower than that of the controls, respectively. Rough hair coats, lethargy, and excessive lacrimation were observed for all animals in the 1,200 and 2,400 mg/kg dose groups. Kidney effects were seen in all treated male rats, with a dose-related increase in severity. The kidney effects were characterized by degeneration of epithelium in the convoluted tubules, granular casts with tubular lumens, primarily in the outer stripe of the outer medulla, and regeneration of the tubular epithelium. Hyaline droplets were observed in the epithelium of the proximal convoluted tubules in all groups of male rats including vehicle controls.

In a NTP 13-week study, male and female B6C3F_1 mice were dosed by oral gavage with 0, 125, 250, 500, 1,000 or 2,000 mg/kg *d*-limonene for five days/week. At 2,000 mg/kg, 1/10 males and 2/10 females died before the end of the study; 1/10 females in the 500 mg/kg group also died before study termination. Several other animals also died as a result of gavage error. Mean body weights were 10% lower than control for male mice and 2% lower than control for female mice for the 1,000 and 2,000 mg/kg groups. Clinical signs of rough hair coats and decreased activity were reported for the two highest dose levels.

Male rats were dosed by oral gavage with 0, 2, 5, 10, 30 or 75 mg/kg *d*-limonene 5 days/week for 13 weeks. Linear regression analyses indicated increased relative kidney and liver weights at 30 and 75 mg/kg. Histological examination showed changes in the kidney characterized by hyaline droplet formation, granular casts and multiple cortical changes. Exacerbation of hyaline droplet formation was reported at the earliest necropsy eight days after administration at the 10 mg/kg dose level.

In a two-year NTP bioassay, male and female F344/N rats were dosed with 0, 75 or 150 mg/kg or 0, 300 or 600 mg/kg *d*-limonene for five days/week. Mean body weights for the 150 mg/kg male rats were generally 4-7% lower than vehicle controls from week 2 to study termination. Mean body weights of the 600 mg/kg females were generally 4-7% lower than vehicle controls from week 28 to study termination. No treatment-related clinical signs were reported for the duration of the study. Survival of the 150 mg/kg male

group was significantly greater than that of the vehicle alone after week 81. Survival of the 600 mg/kg female group was significantly lower than that of the vehicle controls after week 39. In the male rat kidneys, a dose-related increase was observed in the incidence of mineralization and epithelial hyperplasia. A dose-related increase in the severity of spontaneous nephropathy was reported in the treated male rats. Increased incidences in tubular cell hyperplasia and neoplasia were also reported in dosed male rats. Tubular cell adenoma incidence in 150 mg/kg male rats and tubular cell adenoma or tubular cell carcinomas (combined) in dosed male rats were significantly greater than vehicle controls. There was no evidence of carcinogenic activity of *d*-limonene for female rats receiving 300 or 600 mg/kg. The NOAEL for male rats (excluding the kidney effects) is 150 mg/kg/day (see below on the relevance of the male rat kidney effects for human risk assessment). The NOAEL for female rats is 300 mg/kg/day based on low survival in the 600 mg/kg dose group.

In a NTP two-year bioassay, male and female B6C3F_1 mice were dosed by oral gavage with 0, 250, or 500 mg/kg or 0, 500 or 1,000 mg/kg *d*-limonene, respectively, five days a week. Mean body weights for the 1,000 mg/kg female mice administered 1,000 mg/kg were generally 5-15% lower than vehicle controls from week 28 to study termination. No treatment related clinical signs were reported for the duration of the study. Survival of the 250 mg/kg male group was significantly lower than that of the vehicle controls by study termination. In the 500 mg/kg males, livers exhibited presence of cells with abnormal numbers of nuclei and cytomegaly. There was no evidence of carcinogenic activity of *d*-limonene for male or female B6C3F_1 mice at the dose levels tested. The NOAEL for male mice is 250 mg/kg/day based on liver effects at 500 mg/kg/day. Although there was reduced survival in the 250 mg/kg male mice, NTP did not considered this to be dose-related. The NOAEL for female mice is considered to be 500 mg/kg/day based on decreased survival and lower body weights (5 - 15%) in the 1,000 mg/kg dose group.

The kidney changes seen in male rats administered limonene have been well characterized, and are known to be specific to the male rat and of no significance in human risk assessment.

Genotoxicity

Given the structural similarity between the members of this chemical category, the substances in this category exhibit low genotoxic potential *in vitro.*

Mutagenicity/genotoxicity testing has been performed on three members of this chemical category, including a complete battery of *in vitro* genotoxicity tests using limonene. No evidence of mutagenicity was observed when limonene was incubated with *Salmonella typhimurium* strains TA98, TA100, TA102, TA1535, TA1537, and TA1538 with and without S-9 metabolic activation at concentrations up to and including 150,000 µg/plate. Limonene did not induce chromosomal aberrations when incubated with Chinese hamster ovary cells at a concentration of 50-500 µg/ml, nor did it induce sister chromatid

exchanges in Chinese hamster ovary cells at concentrations of 16.2-162 μg/ml. In a mouse lymphoma forward mutation assay, limonene was negative in L5178Y cells with and without S-9 metabolic activation up to a maximum concentration of 100 μg/ml. When incubated with Syrian hamster embryo cells up to 100 μg/ml or 3 mM, limonene did not induce statistically significant cell transformation. The effects of limonene on gap junction intercellular communications were also tested at concentrations up to 1 mM in Syrian hamster embryo cells, and showed no effects.

In an *in vitro* chromosome aberration test with human lymphocytes, myrcene did not induce chromosomal aberrations at concentrations up to 1,000 μg/ml with and without metabolic activation. When incubated with Chinese hamster ovary cells in a V79- HPRT Gene Mutation Assay, myrcene was not mutagenic with or without metabolic activation. In sister chromatid exchange (SCE) tests with human lymphocytes, myrcene did not induce sister chromatid exchanges at concentrations up to 1,000 μg/ml with or without metabolic activation. Additionally, there was no evidence of genotoxicity when myrcene was incubated with V79 and hepatic tumor (HPT) Chinese hamster cells at concentrations up to 500 μg/ml in SCE assays. In fact, myrcene reduced the SCE inducing effect of S-9 mix activated cyclophosphamide in human lymphocytes and Chinese hamster ovary (CHO) cells, and aflatoxin B1 in V79 and HTC Chinese hamster cells in a dose dependent manner.

No evidence of mutagenicity was observed when sweet orange peel oil was incubated with *Salmonella typhimurium* strains TA98, TA100, TA1535, TA1537, and TA1538 with and without S-9 metabolic activation at concentrations up to 5000 μg/plate. In a mouse lymphoma forward mutation assay, sweet orange peel oil was positive in L5178Y cells with and without S-9 metabolic activation up to a maximum concentration of 75 μg/ml but only at highly toxic concentrations. The authors noted that that positive results in this assay may be associated with changes in physiologic culture conditions (pH and osmolality). Negative results were obtained with sweet orange peel oil in the Rec DNA repair assay using *Bacillus subtilis* strains H17 and M45.

In eighteen separate *in vitro* tests on the mutagenicity and genotoxicity of limonene, myrcene, and sweet orange peel oil; the majority was negative, with the exception of the mouse lymphoma assay using sweet orange peel oil. This result is questionable given the culture conditions present and the negative results of the mouse lymphoma assay using limonene since limonene is the majority (greater than 90%) constituent of sweet orange peel oil.

Two *in vivo* genotoxicity assays are available for two substances in this chemical category. In an *in vivo* mammalian spot test, no evidence of mutagenicity was reported when mouse embryos were treated *in utero* with 215 mg/kg/day limonene on days 10 -11 of gestation.

In an *in vivo* cytogenetic bone marrow assay, *beta*-myrcene (100, 500 or 1,000 mg/kg) was orally administered *via* gavage to up to male and female Wistar rats. A dose- related increase in the mitotic index in bone marrow cells was reported for rats administered the

test substance. The authors commented that this might be an interaction between *beta*-myrcene, which is known to induce CYP-450 enzymes, and colchicine, which arrests cell division at metaphase. *beta*-Myrcene may have increased the bioavailability of colchicine leading to the increase in mitotic index observed in the experiment. No significant increases in chromosomal aberrations were reported in the treated animals at either 24 or 48 hours. The authors concluded that given the results, *beta*-myrcene was not clastogenic to the rat when orally administered at dose levels up to 1,000 mg/kg. Based on the results of this *in vivo* genotoxicity assay and the numerous *in vitro* genotoxicity assays, it is unlikely that any of these materials would exhibit a significant genotoxic potential *in vivo*.

Reproductive Toxicity

Selected repeat dose toxicity studies were included in this toxicity profile. For summaries on all conducted studies, see the U.S. HPVIS.

beta-Myrcene was administered *via* gavage to female Wistar rats at dose levels of 250, 500, 1,000 and 1,500 mg/kg of *beta*-myrcene from the 15th day of gestation until weaning of the offspring which was day 21 postnatal. Fertility was impaired in female offspring exposed to 1,000 or 1,500 mg/kg *beta*-myrcene.

In a one-generation reproductive toxicity study, male and female Wistar rats were dosed by oral gavage with 0, 100, 300 or 500 mg/kg *beta*-myrcene. The exposure period was 91 days prior to and during the mating period for the males and 21 days prior to and during the mating period for females, pregnancy, and lactation until 21 days post parturition. Neither deaths nor signs of toxicity were reported in male rats at any dose level. No statistically significant differences in body weight gain were reported between control and test animals. A slight increase in liver and kidney weights was reported for treated male (highest dose only) and female rats. No morphological alterations of the liver or testis tissue were revealed upon microscopic examination. No effects were reported on the number of spermatids in the testis or on the number of spermatozoa in the cauda epididymis. No adverse effects on body weight gain and no other signs of toxicity were observed in treated female rats during the pre-mating or mating periods. No treatment related effects were reported on fertility as measured by the mating index and pregnancy index upon comparison to controls. At the highest dose level, a slight increase in the resorption rate and a parallel decrease in the ratio of live fetuses per implantation site were reported. Increases in the occurrence of fetal skeleton abnormalities between control and treated groups were reported at the 500 mg/kg level. No adverse effects were reported on duration of pregnancy, labor, pup mortality, and maternal or offspring weight changes. Slight delays in incisor eruption (300 mg/kg) and eye opening (100, 300 mg/kg) were reported but were not dose-related. The authors attributed the increase in skeletal abnormalities at the highest dose level tested to known strain-specific anomalies including increases of dislocated sternums, and lumbar extra ribs. The authors concluded that the NOAEL for toxic effects on fertility and general reproductive performance *via* the oral route was 300 mg /kg for *beta*-myrcene.

Female rats were dosed by oral gavage with 0, 375, 750 or 1,500 mg/kg sweet orange peel for seven days prior to and through cohabitation, gestation, delivery and a four day lactation period. No deaths occurred at any dose level. Statistically significant numbers of rats from all three dose groups experienced excess salvation during the pre-mating and gestation periods, and during the lactation period for high-dose animals. The dosed rats had decreased weight gains compared to the control rats during the seven day premating period. Absolute and relative maternal food consumption was significantly decreased for the 750 and 1,500 mg/kg dose groups during the seven day premating period. No treatment related effect on mating performance or fertility was reported at any dose level. A significant increase in stillbirths and pup deaths was reported for the highest dose group compared to the control group (see next section for developmental effects).

Given the results of three reproductive toxicity assays using sweet orange peel oil predominantly composed of *d*-limonene and *beta*-myrcene, it may be concluded that the substances within this chemical category exhibit low reproductive toxicity potential.

Developmental Toxicity

Pregnant female Wistar rats were dosed by oral gavage with 0, 591 or 2,869 mg/kg *d*-limonene on days 9-15 of gestation. At the highest dose level, increases in maternal mortality and decreases in maternal and fetal body weights were reported. Additionally at the highest dose level, delayed ossification of fetal metacarpal bones and proximal phalanx and decreased weights of the thymus, spleen, and ovaries were reported. The NOAEL for both maternal and offspring toxicity was reported to be 591 mg/kg.

Pregnant Japanese white rabbits were administered 0, 250, 500 or 1,000 mg/kg *d*-limonene on days 6 to 18 of gestation. Increased maternal mortality was reported at the highest dose level. Significant decreases in maternal body weight gain and food consumption were temporarily observed at the 500 and 1,000 mg/kg dose levels. No treatment related effects were reported for the offspring. The NOAEL for maternal toxicity was reported to be 250 mg/kg/day. The NOAEL for offspring toxicity was reported to be greater than 1,000 mg/kg/day.

Pregnant ICR mice were administered 0, 591 or 2,363 mg/kg *d*-limonene on days 7 to 12 of gestation. Significant decreases in body weight gain were reported for pregnant ICR mice administered the highest dose level of *d*-limonene. In the offspring, increased incidence of fused ribs compared to that of the controls, delayed ossification of some bones and decreased body weight gain were reported at the highest dose level tested. The NOAEL for both maternal and offspring toxicity was reported to be 591 mg/kg/day.

Pregnant Wistar rats were administered 0, 250, 500 or 1,200 mg/kg *beta*-myrcene on gestational days 6-15. The vehicle was corn oil. Decreased maternal weight gain was reported at the 1,200 mg/kg dose. Increased fetal skeletal malformations were reported at the 1,200 mg/kg dose level. The NOAEL for both maternal and offspring toxicity was

reported to be 500 mg/kg/day.

beta-Myrcene was administered *via* gavage to female Wistar rats at dose levels of 250, 500, 1,000 or 1,500 mg/kg from pregnancy day 15 until weaning of the offspring, which was day 21 postnatal. Mortality, weight gain and post-natal development were evaluated. Reproductive capacity was assessed in the exposed offspring upon reaching maturity (120 days). No adverse effects were noted in the offspring at the lowest dose level tested. Decreased body weight, increased perinatal mortality, and delayed developmental landmarks were noted at the 500, 1000 and 1500 mg/kg dose levels. Fertility was impaired in female offspring exposed to the two highest doses of *beta*-myrcene. The NOAEL for peri- and post-natal development was set at 250 mg/kg/day.

Female rats were dosed by oral gavage with 0, 375, 750 or 1,500 mg/kg sweet orange peel for seven days prior to and through cohabitation, gestation, delivery and a four day lactation period. No deaths occurred at any dose level. Statistically significant numbers of rats from all three dose groups experienced excess salvation during the premating and gestation periods, and during the lactation period for high-dose animals. The dosed rats had decreased weight gains compared to the control rats during the seven-day premating period. Absolute and relative maternal food consumption was significantly decreased for the 750 and 1500 mg/kg/day dose groups during the seven day premating period. No treatment related effects were reported on maternal body weight, changes in body weight, and absolute and relative feed consumption during the lactation period. No treatment related effect on mating performance or fertility was reported at any dose level. A significant increase in stillbirths and pup deaths was reported for the highest dose group compared to the control group. The treatment with sweet orange oil had no effect on the incidence of malformations or gross lesions in the pups. The NOAEL for this study was reported to be less than 375 mg/kg/day for maternal toxicity and 750 mg/kg/day for offspring development.

Given the results of six developmental toxicity assays using limonene, sweet orange oil and *beta*-myrcene, it may be concluded that the substances within this chemical category exhibit low developmental toxicity potential.

Key Study/Critical Effect for Screening Criteria

The toxicity data on d-limonene will be used as read-across to CAS No. 68647-72-3. The kidney changes seen in male rats administered limonene have been well characterized, and are known to be specific to the male rat and of no significance in human risk assessment. Thus, the male rat kidney effects will not be considered in the determining the critical effect for a drinking water guideline value.

In the NTP two-year rat bioassay, the NOAELs for male and female rats were 150 and 300 mg/kg/day, respectively. In the NTP two-year mouse bioassay, the NOAELs for male and female mice were 250 and 500 mg/kg/day, respectively.

The lowest NOAEL is 150 mg/kg/day for male rats in the NTP 2-year bioassay based on liver effects. Adjusting for 5 days/week to 7 days/week, results in a NOAEL for continuous exposure of 107 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 107/100 = 1.1 mg/kg/day

Drinking water guidance value = 3.8 ppm

U.S. EPA HPVIS database: http://www.epa.gov/chemrtk/hpvis/index.html

Toxicity Profile

Tetrakis(hydroxymethyl)phosphonium sulfate
(CAS No. 55566-30-8)

Toxicity information is provided on tetrakis(hydroxymethyl)phosphonium sulfate (THPS) and its structural analog tetrakis(hydroxymethyl)phosphonium chloride (THPC)

Metabolism

A metabolism study on rats has been conducted using ^{14}C-radiolabelled THPS. THPS was not found in rat urine. However, three metabolites were present, identified as trihydroxymethyl phosphine oxide, bishydroxymethylphosphonic acid and possibly a formaldehyde adduct of the trihydroxy compound (IPCS, 2000).

Acute Toxicity

No female mice died when given an oral dose of 200 mg/kg THPS (IPCS, 2000). The oral LD_{50} value of THPC (as a 75% solution) was reported to be 282 mg/kg in male rats; 575 mg/kg in male and female rats combined; 185 mg/kg in male rats; and 161 mg/kg in female rats (IPCS, 2000).

No deaths occurred when rats were treated with THPS at 2,000 mg/kg (IPCS, 2000).

The 4-hour LC_{50} in rats was 5.5 mg/L when exposed nose-only to a respirable aerosol (IPCS, 2000).

Irritation

THPS was not irritating to the skin of rabbits; however, repeated application resulted in severe skin irritation (IPCS, 2000). THPS is a severe eye irritant in rabbits (IPCS, 2000).

Sensitization

THPS is a skin sensitizer to guinea-pigs (IPCS, 2000).

Repeat Dose Toxicity

In a 13-week NTP oral gavage study, male and female F344/N rats were given 0, 5, 10, 20, 40 or 60 mg/kg THPS five days/week. Death occurred in the 60 mg/kg male rats (3/10) prior to the end of the study; all other rats survived to the end of the studies. Final mean body weights were 5%, 15%, and 22% lower than those of the vehicle controls for

males that received 20,40,or 60 mg/kg, and from 7% to 19% lower for all groups of dosed female rats. Diarrhea occurred in all groups of dosed rats during weeks 3 and 4. Vacuolar degeneration of the hepatocytes occurred in all males receiving $\geq$10 mg/kg, in all females receiving 40 or 60 mg/kg, and in 5/10 females receiving 20 mg/kg. The severity of this lesion was greatest in the 60 mg/kg group. In other groups, the severity was generally minimal to mild. Lymphoid depletion in the spleen or thymus was observed in the three males in the 60 mg/kg group which died before the end of the studies. Bone marrow hypoplasia was diagnosed in 3/10 male and 4/10 female rats in the 60 mg/kg groups.

In a 13-week NTP oral gavage study, male and female B6C3F$_1$ mice were given 0, 5, 10, 20, 40 or 60 mg/kg THPS 5 days/week. Females (1/10) that received 60 mg/kg and 2/10 males and 1/10 females that received 40 mg/kg died before the end of the studies. Final mean body weights of mice that received 20, 40, or 60 mg/kg were 4%, 7%, and 11% lower than those of the vehicle controls for males and 3%, *5%*, and 11% lower for females. Periportal vacuolar degeneration occurred in all mice that received 60 mg/kg (minimal to moderate severity), 10/l0 male and 9/10 female mice that received 40 mg/kg, and 8/10 male mice that received 20 mg/kg (minimal to mild severity).

In the 2-yr NTP study, male and female F344/N rats were given by oral gavage 0, 5, or 10 mg/kg THPS, 5 days/week for 103 to 104 weeks. Survival of male rats was reduced for the low dose (after week 102) and the high dose (after week 67) groups given THPS compared with that of the vehicle controls; survival at terminal kill was as follows: vehicle control, 28/50; low dose, 13/50; high dose, 16/50. Mean body weights of rats dosed with THPS were comparable to those of the vehicle controls. There was an increase in the incidence of hepatocellular lesions, primarily cytoplasmic vacuolization, which was dose-related. The incidence of these lesions were: in males, 2/50, 4/50, 9/49, at 0, 5, 10 mg/kg; in females, 1/49, 3/50, 8/49 at 0, 5, and 10 mg/kg. The incidences of mononuclear cell leukemia in 5 mg/kg male rats was somewhat greater than those in the vehicle controls (THPS: 30/50; 36/50; 20/50). This marginal increase in the incidences of hematopoietic system tumors was not considered related to chemical exposure, since they were significant only by the life table tests and were not dose related. The incidence of cystic degeneration of the liver was also increased in male rats (7/50, 15/50, and 14/49 at 0, 5, and 10 mg/kg). The LOAEL for this study is 5 mg/kg with no NOAEL.

In the 2-yr NTP study, male and female B6C3F$_1$ mice were given by oral gavage 0, 5, or 10 mg/kg THPS, 5 days/week for 103 to 104 weeks. There was no difference in survival or mean body weights between the vehicle controls and mice dosed with THPS. There was an increase in the incidence of hepatocellular lesions, primarily cytoplasmic vacuolization in female mice only, but it was not dose-related. The incidences of this lesion were: in males, 0/48, 1/49, 0/50 at 0, 5, and 10 mg/kg; in females, 6/50, 13/50, and 7/49 at 0, 5, and 10 mg/kg. The LOAEL for this study was 5 mg/kg, with no NOAEL.

There was also focal hyperplasia of the adrenal medulla in the 10 mg/kg male mice. The 5 mg/kg male mice had an increased incidence of malignant lymphomas when compared with vehicle controls (2/50; 9/50; 0/50). This marginal increase in the incidences of

hematopoietic system tumors was not considered related to chemical exposure, since they were significant only by the life table tests and were not dose related.

Genotoxicity

Salmonella microsomal assays in the presence or absence of metabolic activation have shown uniformly negative results for THPS (IPCS, 2000). THPS induced forward mutations in mouse lymphoma L5178Y cells without metabolic activation; it was not tested in the presence of S9 (NTP, 1987). Another mouse lymphoma assay showed mutations both in the presence and absence of metabolic activation (IPCS, 2000).

Increased chromosomal aberrations were detected at metaphase in CHO cells treated with THPS in the presence or absence of S9 from liver of Aroclor-treated rats (IPCS, 2000). Anaphase analysis of THPS-treated CHO cells also showed that chromosomal aberrations were produced along with abnormal spindles (IPCS, 2000).

The results of an *in vitro* assay for unscheduled DNA synthesis in a primary culture of rat hepatocytes were negative (IPCS, 2000).

THPS was administered to mice by gavage or dermal application or by mixing treated cloth with the animals' feed. The urine of these dosed mice was analyzed for mutagenicity in the Salmonella microsome assay, and frequencies of micronuclei and chromosomal aberrations were evaluated in bone marrow cells. None of these investigations demonstrated mutagenic activity for THPS (NTP, 1987; IPCS, 2000).

THPS was negative in rats and mice in dominant lethal assays (IPCS, 2000).

Carcinogenicity

Two-year NTP studies have been conducted in F344/N rats and $B6C3F_1$ mice by administering 0, 5, or 10 mg/kg THPS by oral gavage, 5 days per week for 103 or 104 weeks (NTP, 1987). The incidences of mononuclear cell leukemia in the low dose male rats administered THPS was somewhat greater than those in the vehicle controls. Low dose male mice administered THPS had an increased incidence of malignant lymphomas when compared with vehicle controls (2/50; 9/50; 0/50). These marginal increases in the incidences of hematopoietic system tumors were not considered related to chemical exposure, since they were significant only by the life table tests and were not dose-related.

Reproductive/Developmental Toxicity

Pregnant CD rats were given by oral gavage 0, 15, 30 or 60 mg/kg THPS (as a 75% solution) during gestational days 6 to 15. Maternal body weight gain was significantly lower from gestational day 12 until the end of the study in the 60 mg/kg group. There

were minor signs of maternal toxicity in the 30 mg/kg group. The incidence of fetuses showing extra thoraco-lumbar ribs was significantly higher in the 60 mg/kg group compared to controls. The maternal and developmental NOAELs for this study were 30 mg/kg-day (IPCS, 2000).

Pregnant New Zealand rabbits were given by oral gavage 0, 6, 18 or 60 mg/kg THPS (as a 75% solution) during gestational days 7 to 19. Maternal body weight gain was significantly lower in the 60 mg/kg group compared to the controls. There was increased incidence (42/120) of fetuses with eye malformation and some with additional hydrocephaly or limb/phalangeal reduction defects in the 60 mg/kg group. An increased incidence of specific skeleton variation was also observed. No adverse effects were noticed in the 6 or 18 mg/kg groups. The maternal and developmental NOAELs for this study is 18 mg/kg-day (IPCS, 2000).

Key Study/Critical Effect for Screening Criteria

The critical effect for a drinking water guideline value is liver effects in male and female rats and female mice at 5 mg/kg/day in the two-year study. To adjust for continuous exposure, the LOAEL is adjusted by converting 5 days/week to 7 days/week.

$LOAEL_{adjusted}$ = 5 * 5/7 = 3.6 mg/kg/day

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (LOAEL to NOAEL)

Oral RfD = 4/1,000 = 0.004 mg/kg/day

Drinking water guideline: 0.01 ppm

COFFEE EXTRACT

This dossier on coffee extract does not represent an exhaustive or critical review of all available data. Rather, it presents the most critical studies pertinent to the risk assessment of coffee extract in its use in hydraulic fracturing fluids. The information presented in this dossier was obtained from the ECHA database that provides information on chemicals that have been registered under the EU REACH (ECHA). Where possible, study quality was evaluated using the Klimisch scoring system (Klimisch *et al.*, 1997).

I. SUBSTANCE IDENTIFICATION

Chemical Name: Coffee, bean, roasted, extract

CAS RN: 68916-18-7

Molecular formula: UVCB substance

Molecular weight: UVCB substance

Synonyms: Coffee extract; coffee, bean, roasted, extract

Table 1 shows all of the constituents found in roasted arabica and robusta coffees.

Table 1: Composition of Medium-Roasted Coffee (Clarke, 1987; IARC, 1991)

Components	**Typical average content (dry basis, %)**		**% extractable with water, 100°C[a]**
	Arabica	**Robusta**	
Alkaloids (caffeine)	1.3	2.4	75 - 100
Trigonelline (including roasted by-products)	1.0	0.7	85 - 100
Minerals (as oxide ash)	4.5	4.7	90
Acids			
Residual chlorogenic	2.5	3.8	100
Aquinic	0.8	1.0	100
Aliphatic	1.6	1.6	100
Sugars			
Sucrose	0.0	0.0	-
Reducing	0.3	0.3	100

Polysaccharides (unchanged from green)	33	37	10
Lignin	2.0	2.0	0
Pectins	3.0	3.0	-
Proteinaceous compounds			
Protein	10	10	15 – 20
Free amino acids	0.0	0.0	-
Lipids (coffee oil)	17	11	1
Caramelized or condensation products (*e.g.*, melanoidins) by difference	23	22.5	20-25
Volatile substances other than acids	0.1	0.1	40-80

[a]Maier (1981), for normal household brewing

II. PHYSICO-CHEMICAL PROPERTIES

Table 2: Overview of the Physico-chemical Properties of Coffee Extract

Property	**Value**	**Klimisch score**	**Reference**
Physical state at 20°C and 101.3 kPa	Viscous liquid	2	ECHA
Melting point	ca. -16.82 to -15.95°C	1	ECHA
Boiling point	>102.21°C	1	ECHA
Density	1.234 g/cm^3 @ 20°C	1	ECHA
Vapor pressure	21.8 Pa @ 20°C	1	ECHA
Partition coefficient (log K_{ow})	<0.36 @ 25°C	1	ECHA
Water solubility	2.85 mg/L @ 25°C	1	ECHA
Flash point	No flash to boiling.	1	ECHA
Auto flammability	>600°C	1	ECHA

III. ENVIRONMENTAL FATE PROPERTIES

A. Summary

Coffee extract is inherently biodegradable and is expected to have a low potential for bioaccumulation. The potential for adsorption is unknown; however, the low octanol water partition coefficient for coffee extract suggests that it is low. The acute toxicity by the oral and dermal routes is low.

B. Biodegradation

Coffee extract is inherently biodegradable. In an OECD 301D test, degradation was 50.2% after 28 days (ECHA) [Kl. score = 1].

C. Environmental Distribution

Adsorption/desorption

No experimental data are available for coffee extract. Coffee extract is an UVCB substance containing a wide range of different constituents (see Table 1); thus, a K_{oc} value cannot be calculated.

D. Bioaccumulation

No bioconcentration studies have been conducted on coffee extract. Coffee extract is not expected to bioaccumulate based on the experimental log K_{ow} of <0.36 (ECHA).

IV. HUMAN HEALTH HAZARD ASSESSMENT

A. Summary

The information on the human health hazard for coffee extract includes primarily data on caffeine, the pharmacologically active constituent of coffee extract, as well as the extract itself. Coffee extract is not irritating to the skin or eyes. Caffeine consumption up to 400 mg caffeine/day in healthy adults is not associated with overt, adverse cardiovascular effects, behavioral effects, reproductive and developmental effects, acute effects, or bone status. Also, consumption up to 300 mg caffeine/day in healthy pregnant women is generally not associated with adverse reproductive and developmental effects.

B. Pharmacokinetics

Caffeine is rapidly and completely adsorbed in humans, with approximately 99% absorbed within 45 minutes of consumption (Carillo and Benitez, 2000). Plasma caffeine levels may be influenced by the diet or route of exposure, but peak plasma levels occur approximately 15 to 120 minutes after consumption (Mandel, 2002; Beach *et al.*, 1984; Bonati *et al.*, 1984; Collomp *et al.*,

1991). Caffeine is water soluble and is rapidly distributed throughout the body, detected in all bodily fluids, including saliva, breast milk, urine and semen (Beach *et al.*, 1984). Caffeine elimination follows first-order kinetics (Newton *et al.*, 1981), with the plasma half-life of caffeine at approximately 3 to 6 hours in healthy adults and does not accumulate in body fat or other tissues (Kaplan *et al.*, 1997; Nawrot *et al.*, 2003). Caffeine is rapidly metabolized and excreted (1-3 mg/kg/minute) in the urine (Kaplan *et al.*, 1997), and varies between species, with a slightly different metabolic route noted in rats (Nawrot *et al.*, 2003).

C. Acute Toxicity

Animal Studies

The oral LD_{50} value of an aqueous extract of roasted and ground beans of *Coffea canephora robusta* containing 7.5% caffeine was between 2,000 and 5,000 mg/kg (ECHA) [Kl. score = 1].

No acute inhalation studies are available on coffee extract. The 4-hour LC_{50} value of a caffeine aerosol in rats is 4.94 mg/L (ECHA) [Kl. score = 2].

No acute dermal studies are available on coffee extract. The dermal LD_{50} value of an aqueous solution of caffeine in rats is >2,000 mg/kg (ECHA) [Kl. score = 2].

Human Studies

Studies in human have focused on caffeine, the pharmacologically active component in coffee. The fatal acute oral dose is estimated at 10 and 14 g (approximately 160 to 230 mg/kg for a 60 kg person) (Hodgman, 1998). The serum caffeine concentration is the most reliable indicator of potential caffeine toxicity, with a serum caffeine concentration >100 μg/ml considered lethal in humans (Mrvos *et al.*, 1989). Human caffeine consumption at up to 10 g has caused convulsions and vomiting, with recovery in six hours (Dreisbach, 1974). An acute dose of one gram caffeine can cause adverse effects, progressing from restlessness, nervousness, and irritability to delirium, emesis, neuromuscular tremors and convulsions (IOM, 2004). However, caffeine consumption through the day at up to 900 mg has been reported without adverse effects (Nawrot *et al.*, 2003).

D. Irritation

Coffee silverskin extracts was not considered a skin irritant when tested in an *in vitro* reconstructed human epidermis test (ECHA) [Kl. score = 1].

Coffee, bean, roasted, extract was not considered an eye irritant when tested in a bovine corneal opacity and permeability test (ECHA) [Kl. score = 1].

E. Sensitization

No studies are available.

F. Repeated Dose Toxicity

<u>Oral</u>

Male and female rats were given in their drinking water 0, 25, 50, or 100% with either instant or brewed coffee for 91 days. The average daily intakes of caffeine were 0, 20, 40, or 80 mg/kg-day for the brewed coffee and slightly lower intakes for the instant coffee. At study termination, the kidneys of the 100% male coffee groups had enlarged kidneys based on both absolute and relative weights. In the females, liver and kidneys were enlarged in all rats given brewed coffee, although the relative weights were significantly higher only in the 100% group. In the ≥50% instant coffee groups, both absolute and relative liver and kidney weights were increased, although there was no clear dose-response pattern. Histopathologic examination showed no treatment-related effects. In the absence of corresponding histopathologic changes, the liver and kidney weight changes were considered to be adaptive changes and not adverse. The NOAEL for this study is 100% coffee in drinking water, which corresponds to 80 mg/kg-day (Nolen, 1981; ECHA) [Kl. score = 2].

In an NTP study, male and female F344 rats were dosed by oral gavage with 0, 188, 375, 750, 1,500, or 3,000 ppm caffeine for 90 days. The average daily intakes were: 0, 19.7, 42, 85.4, 151, or 272 mg/kg-day for males; and 0, 23, 51, 104, 174, or 287 mg/kg-day for females). Body weight gain was reduced in all treated groups but was only significant in the 3,000 ppm animals (26% and 20% for males and females, respectively). Water consumption was decreased in the 3,000 ppm animals; it was increased in the 375 and 750 ppm groups. The only treatment-related effects observed was cellular enlargement in the salivary gland, which was dose-dependent. This effect in the salivary gland was considered an adaptive response as a result of the pharmacological effect of caffeine (sympathomimetic) and not an adverse effect. The NOAEL for this study is 1,500 ppm, which corresponds to 151 and 174 mg/kg-day for males and females, respectively (ECHA) [Kl. score = 2].

Inhalation

No studies are available.

Dermal

No studies are available.

G. Genotoxicity

In Vitro Studies

Instant and home brew coffees (caffeinated and decaffeinated) were evaluated for genotoxicity in an in vitro chromosomal aberration test using human lymphocytes with or without metabolic activation (S9 mix). Chromosomal aberrations were increased with all coffee samples with or without S9, although there was less of an increase with S9. Pure caffeine tested with or without S9 at doses equivalent to the levels in the caffeine-containing coffees did not induce a statistically significant increase in chromosomal aberrations (Aeschbacher et al., 1985; ECHA) [Kl. score 2].

Instant and home brew coffees (caffeinated and decaffeinated) were evaluated for mutagenicity in an in vitro bacterial reverse mutation assay with or without metabolic activation (S9 mix). The *S. typhimurium* strains were TA 98, TA 100, TA1535, TA 1537, and TA 1538. A mutagenic response was observed with TA 100 in the absence of S9, but not with S9. None of the other

strains showed a mutagenic response with or without S9 (Aeschbacher and Würzner, 1980; ECHA) [Kl. score = 2].

Five Americano coffees from selected coffee chains were evaluated for mutagenicity in an in vitro bacterial reverse mutation assay with or without metabolic activation (S9 mix). The *S. typhimurium* strains were TA 98, TA 100, and TA 1535. There were no mutagenic responses with or without metabolic activation (Liu et al., 2017; ECHA) [Kl. score = 2].

In Vivo Studies

Male Swiss OF-1 mice were dosed by oral gavage with 0, 500, 1,000, 2,000, or 3,000 mg/kg instant coffee for five consecutive days. There was no treatment-related increase in the frequency of micronuclei in bone marrow cells (Aeschbacher et. al., 1984 ECHA) [Kl. score = 2].

H. Carcinogenicity

No carcinogenicity studies are available.

I. Reproductive/Developmental Toxicity

Animal Studies

A one-generation reproductive toxicity study was conducted in rats. Male and female rats were given in their drinking water 0, 25, 50, or 100% with either instant or brewed coffee. The average daily intakes were 0, 20, 40, or 8 mg/kg-day for the brewed coffee and slightly lower intakes for the instant coffee. Exposure of parental animals were for 91 days and during mating. Exposure continued through the first gestation period and through weaning. Ten days later, the females were mated the second time and were sacrificed on GD 13 or 21. There were no indications of reproductive or developmental toxicity (Nolen, 1981; ECHA) [Kl. score = 2].

Human Studies

Studies in human have focused on caffeine, the pharmacologically active component in coffee. Studies that evaluated the potential teratogenicity of caffeine have been discussed in a review (Christian and Brent, 2001). In animal studies, caffeine administration to pregnant animals has been found to induce teratogenicity and toxic effects on the development of the fetuses only at doses that also caused toxic effects in the dams (Christian and Brent, 2001). Christian and Brent (2001) concluded that studies reporting positive teratogenic effects were administering large doses of caffeine that were far greater than human consumption and were providing the caffeine via gavage, which results in much higher peak serum caffeine levels and therefore overstates toxicity potential. Neither rodents nor humans could attain such peak exposures by consuming solutions of caffeine over several hours, the usual mode of human caffeine consumption.

There have been questions raised on whether high intake of coffee or caffeine may increase the risk of miscarriage. Caffeine crosses the placenta and increases maternal catecholamine levels (Goldstein and Warren, 1962). The American College of Obstetricians and Gynecologists (2010) have concluded the following: “Moderate caffeine consumption (less than 200 mg per day) does not appear to be a major contributing factor in miscarriage or preterm birth. The relationship of

caffeine to growth restriction remains undetermined. A final conclusion cannot be made at this time as to whether there is a correlation between high caffeine intake and miscarriage."

The American College of Obstetricians and Gynecologists (2010) have concluded that moderate caffeine consumption (<200 mg/day) does not appear to be a major contributing factor in miscarriage or preterm birth.

A recent systematic review of the potential adverse effects of caffeine consumptions in humans concluded that consumption up to 400 mg caffeine/day in healthy adults is not associated with reproductive and developmental effects. Also, consumption up to 300 mg caffeine/day in healthy pregnant women is generally not associated with adverse reproductive and developmental effects (Wikoff et al., 2017).

J. Human Studies

Caffeine is a stimulant and has been studied for its physiological and behavioral effects. Caffeine increases heart rate and blood pressure, increases diuresis, increases locomotion and alertness, and decreases sleepiness. Clinical studies indicate that doses <450 mg do not increase the risk or severity of cardiac arrhythmia, while acute doses of 150 mg caffeine may decrease heart rate (James, 1991; Green *et al.*, 1996; Myer, 1998). Studies evaluating effects of caffeine on cardiovascular health or serum cholesterol levels have not provided a consistent adverse effect with caffeine consumption (Nawrot *et al.*, 2003).

Nawrot *et al.* (2003) concluded in their review of the effects of caffeine on human health that "for the healthy adult population, moderate daily caffeine intake at a dose level up to 400 mg/day (equivalent to 6 mg/kg body weight/day in a 65-kg person) is not associated with adverse effects such as general toxicity, cardiovascular effects, effects on bone status and calcium balance (with consumption of adequate calcium), changes in adult behavior, increased incidence of cancer and effects on male fertility." It was indicated that habitual daily use of caffeine at greater than 500-600 mg/day (8.3 - 10 mg/kg) (4-7 cups of coffee or 7-9 cups of tea) could be considered a health risk. For women, caffeine intake greater than 400 mg/day (6.7 mg/kg) "may increase the risk of detrusor instability (unstable bladder) development in women" (Nawrot *et al.*, 2003).

A recent systematic review of the potential adverse effects of caffeine consumptions in humans also concluded that consumption up to 400 mg caffeine/day in healthy adults is not associated with overt, adverse cardiovascular effects, behavioral effects, acute effects or bone status (Wikoff et al., 2017).

V. DERIVATION OF TOXICOLOGICAL REFERENCE AND DRINKING WATER GUIDANCE VALUES

The toxicological reference values developed for coffee extract follow the methodology discussed in enHealth (2012). The approach used to develop drinking water guidance values is described in the Australian Drinking Water Guidelines (ADWG, 2011).

A. Non-Cancer

<u>Oral</u>

A 90-day drinking water study on brewed and instant coffee reported no adverse effects up to 80 mg/kg-day (Nolen, 1982). A NTP 90-day oral gavage toxicity study in rats showed no adverse effects up to 174 mg/kg-day (NTP).

In two separate reviews (Nawrot et al., 2003; Wikoff et al., 2017) with the most recent one conducted using a systematic review approach (Wikoff et al., 2003), caffeine consumption in healthy adults up to 400 mg/day is not associated with any adverse health effects. Based on the acceptable daily intake of caffeine in coffee extract, the acceptable daily intake of caffeine of 400 mg/day will be used to derive the oral reference dose and drinking water guidance value for coffee extract.

Oral Reference Dose (oral RfD)

For a 70 kg person, the oral reference dose is 400/70 = 6 mg/kg-day.

Drinking water guidance value

Drinking water guidance value = (animal dose) x (human weight) x (proportion of intake from water) / (volume of water consumed) x (safety factor)

Using the oral RfD,
Drinking water guidance value = (oral RfD) x (human weight) x (proportion of water consumed) / (volume of water consumed)

where:
Human weight = 70 kg (ADWG, 2011)
Proportion of water consumed = 10% (ADWG, 2011)
Volume of water consumed = 2L (ADWG, 2011)

Drinking water guidance value = (5.7 x 70 x 0.1)/2 = <u>20 mg/L</u>

B. Cancer

No studies are available. Thus, a cancer reference value was not derived.

VI. HUMAN HEALTH HAZARD ASSESSMENT OF PHYSICO-CHEMICAL PROPERTIES

Coffee extract does not exhibit the following physico-chemical properties:

- Explosivity
- Flammability
- Oxidizing potential

VII. ENVIRONMENTAL HAZARD ASSESSMENT

A. Summary

Coffee extract has a low acute toxicity concern for aquatic life.

B. Aquatic Toxicity

Acute Studies

Table 3 lists the results of acute aquatic toxicity studies conducted on coffee extract.

Table 3: Acute Aquatic Toxicity Studies on Coffee Extract

Test Species	Endpoint	Results (mg/L)	Klimisch score	Reference
Oncorhynchus mykiss	96-hr LL_{50}	>100 WAF	1	ECHA
Daphnia magna	48-hr EL_{50}	>100 WAF	1	ECHA
Pseudokirchneriella subcapitata	72-hr EL_{50}	>100 WAF (growth)	1	ECHA

Chronic Studies

No studies are available.

C. Terrestrial Toxicity

No studies are available.

D. Calculation of PNEC

The PNEC calculations for coffee extract follow the methodology discussed in DEWHA (2009).

PNEC water

Experimental results are available for three trophic levels. Acute $E(L)L_{50}$ values are available for fish (>100 mg/L WAF), invertebrates (>100 mg/L WAF), and algae (>100 mg/L WAF). On the basis that the data consist of short-term results from three trophic levels, an assessment factor of 100 has been applied to the acute $E(L)L_{50}$ value of 100 mg/L WAF from fish, invertebrates, and algae. The $PNEC_{water}$ is 1 mg/L.

PNEC sediment

There are no toxicity data for sediment-dwelling organisms. The $PNEC_{sed}$ was not calculated using the equilibrium partitioning method because the K_{oc} value cannot be determined.

PNEC soil

There are no toxicity data for terrestrial or soil organisms. The $PNEC_{soil}$ was not calculated using the equilibrium partitioning method because the K_{oc} value cannot be determined.

VIII. PBT Assessment

The methodology for the Persistent, Bioaccumulative and Toxic (PBT) substances assessment is based on the Australian and EU Reach Criteria methodology (DEWHA, 2009; ECHA, 2008). Coffee extract is not readily biodegradable, but it does appear to be inherently biodegradable; thus, it is not expected to meet the screening criteria for persistence.

Based on a measured log K_{ow} of <0.36, coffee extract does not meet the screening criteria for bioaccumulation.

There are no chronic aquatic toxicity studies on coffee extract. The acute $E(L)L_{50}$ values for coffee extract are >1 mg/L for fish, invertebrates, and algae. Thus, coffee extract does not meet the screening criteria for toxicity.

The overall conclusion is that coffee extract is not a PBT substance.

IX. CLASSIFICATION AND LABELING

A. Classification

Not classified.

B. Labelling

No signal word.

C. Pictogram

None.

X. SAFETY AND HANDLING

A. FIRST AID

Eye Contact
In case of contact, immediately flush eyes with plenty of water. If easy to do, remove contact lenses.

Skin Contact
Take off contaminated clothing immediately. Wash thoroughly with soap and water. Get medical attention if irritation develops and persists.

Inhalation
If inhaled, remove from area to fresh air. Get medical attention.

Ingestion
Rinse mouth with water and then drink a glass of water. Get medical attention. Do not induce vomiting. Never give anything by mouth to an unconscious person.

B. FIRE FIGHTING INFORMATION

Extinguishing Media
Water spray, carbon dioxide, foam, dry chemical.

Specific Exposure Hazards
May emit toxic fumes under fire conditions. Depending on conditions, decomposition products may include the following: carbon monoxide, carbon oxides, nitrogen oxides.

Special Protective Equipment for Firefighters
Wear self-contained breathing apparatus.

C. ACCIDENTAL RELEASE MEASURES

Personal Precautions
Use personal protective clothing.

Environmental Precautions
Do not empty into drains.

Steps to be Taken if Material is Released or Spilled
For small amounts: Pick up with absorbent material. Dispose of contaminated material. For large amounts: pump off product.

D. STORAGE AND HANDLING

General Handling
No special measures necessary provided product is used correctly.

Storage
Keep container tightly closed and dry. Store in a cool place.

E. EXPOSURE CONTROLS / PERSONAL PROTECTION

Occupational Exposure Standards

Workplace Australia has not established an occupational exposure limit for coffee extract.

Engineering Controls
None

Personal Protection Equipment

Respiratory Protection: Respiratory protection not required.

Hand Protection: Wear chemical resistant protective gloves.

Skin Protection: Body protection must be chosen depending on activity and possible exposure.

Eye protection*:* Wear safety goggles with side shields.

Other Precautions:
Handle in accordance with good industrial hygiene and safety practice. Wearing of closed work clothing is recommended. Ensure that eyewash stations and safety showers are close to the workstation location.

F. TRANSPORT INFORMATION

Coffee extract is not considered hazardous for purposes of transportation by road or rail. An Australian Dangerous Goods code is not required.

XI. DISPOSAL

Disposal should be in accordance with all local, state, and federal regulations.

XII. REGULATORY INFORMATION

Australian AICS Inventory: Listed.

APPENDIX F.3 HALLIBURTON CLEANSTIMAU

Toxicity Profile

Aluminum sulfate
(CAS No. 10043-01-3)

This environmental assessment on aluminum sulfate has been extracted from the 2010 Priority Substances List Assessment Report. Follow-up to the State of the Science Report, 2000 for Aluminum Chloride, Aluminum Nitrate, Aluminum Sulphate, prepared by Environment Canada and Health Canada (Canada, 2010). The report can be downloaded from: http://www.ec.gc.ca/lcpe-cepa/default.asp?lang=En&n=491F0099-1

Aluminum sulfate, also know as alum, has the chemical formula is $Al_2(SO_4)_3$. It is often represented as $Al_2(SO_4)_3 \cdot 14H_2O$. It may be found in different hydrated forms. The commercial product, called cake alum or patent alum, is an octadecahydrate aluminum sulfate, $Al_2(SO_4)_3 \cdot 18H_2O$.

Aluminum sulfate is used primarily as a coagulant and flocculant in water and wastewater treatment.

Toxicokinetics

Even at moderately elevated levels in the environment, exposure of aluminum leads to only small increases of aluminum in human tissues due to its low bioavailability through all routes of exposure.

Acute Toxicity

An oral LD_{50} in mice was reported to be 6,200 mg Al/kg for $Al_2(SO_4)_3$,although it unclear whether the value refers to Al or to the salt (Sorenson *et al.*, 1974). An oral LD_{50} was estimated to be >730 mg Al/kg in rats and mice in a 14-day study of oral and intraperitoneal administration (Llobet *et al.*, 1987).

Genotoxicity

Comprehensive reviews of the genotoxicity data of various aluminum compounds are available (Krewski et al., 2007; ATSDR, 2008). Generally, aluminum compounds have not been mutagenic in a variety of *in vitro* genotoxicity studies.

Aluminum chloride has been shown to induce micronuclei formation and sister chromatid exchange in human blood lymphocytes (Krewski *et al.*, 2007). In a more recent study, aluminum chloride was cytotoxic, reduced the mitotic index and induced DNA damage in a comet assay and a chromosomal aberration assay conducted with cultured human

lymphoctyes (Lima *et al.*, 2007).

In an in vivo rat chromosomal aberration study, male rats dosed with 17 to 171 mg Al/kg in drinking water for 21 days showed increased chromosomal aberrations, characterized mostly by chromatid breaks, with translocations at the higher doses (Roy *et al.*, 1991).

EFSA (2008) has proposed that the genotoxic effects of aluminum occurs by an indirect mechanisms involving cross-linking of DNA with chromosomal proteins, interaction with microtubule assembly and mitotic spindle functioning, induction of oxidative damage, and damage of lysosomal membranes with liberation of DNAase to explain the induction of structural chromosomal aberrations, sister chromatid exchanges, chromosome loss and formation of oxidized bases in experimental systems. It was concluded that these effects occur at relatively high levels of exposure and would not likely be of relevance for humans exposed to aluminum via the diet.

Carcinogenicity

An increase in gross tumors was reported in male rats and female mice in a one-dose study; few study details were reported (Schroeder and Mitchener, 1975a,b; as reported in ATSDR 2008). Two other studies reported no increased incidence of tumors in rats and mice exposed orally to aluminum compounds (Hackenberg, 1972; Oneda *et al.*, 1994).

Subchronic/Chronic Toxicity Studies (Oral Exposure)

Canada (2010) reviewed the results of 49 subchronic and chronic toxicity studies in adult mice, rats, rabbits, monkeys and dogs. Aluminum was administered orally in drinking water, in the diet or by gavage. The aluminum salts include lactate, chloride, sulfate, nitrate, hydroxide, citrate, maltolate, fluoride and KASAL (basic sodium aluminum phosphate).

Many of the subchronic and chronic toxicity studies did not quantify the concentration of aluminum in the base diet. In those studies where the administered dose was substantially less than the possible baseline dose in the diet, the uncertainty associated with the actual combined dose was increased.

Neurobehavioral effects were reported in adult mice and rats following oral exposure for 90 days or more. Decreased spontaneous motor activity was reported, with the lowest LOEL being 1 mg Al/kg-day in male Sprague-Dawley rats who received aluminum maltolate at this dose in drinking water over a period of one year (Huh *et al.*, 2005). In contrast, Domingo *et al.* (1996) and Colomina *et al.* (2002) found no differences in field activity of Sprague-Dawley rats given 100 mg Al/kg-day of aluminum nitrate (with citrate) in drinking water for periods of four to six months. Other studies have reported decreased motor coordination as measured by performance in the rotarod test, decreased grip strength, and effects on temperature sensitivity and negative geotaxis.

Learning and memory deficits (maze performance, passive avoidance tests) have also been reported. The LOEL for these effects was 6 mg Al/kg-day in Long Evans rats exposed for 90 days to aluminum chloride (plus citrate) via gavage, although there was some ambiguity in the reporting of doses in this study (Bilkei-Gorzo, 1993). However, other investigators did not find effects on similar learning or memory tests. For instance, von Linstow Rolloff *et al.* (2002), reported no effects in male Lister hooded rats given 140 mg Al/kg as aluminum sulfate in drinking water.

Histopathological effects reported in rats and mice included increased damaged or abnormal neurons in specific brain regions (*e.g.*, cerebral cortex and hippocampus, neurofibrillary degeneration and vacuolization of nuclei, and vacuolated astrocytes and vacuolization of neuronal cytoplasm. The LOEL in which these effects were observed was <1 mg Al/kg-day in the Varner *et al.* (1998) and Varner *et al.* (1993) studies in which aluminum nitrate and sodium fluoride (to form aluminum fluoride) was administered in drinking water to male Long Evans rats for periods of 45 to 52 weeks. Petterson *et al.* (1990) observed mild to moderate histopathological effects in testes, liver and kidney, including hepatocyte vacuolization, seminiferous tubule germinal epithelial cell degeneration and tubular-glomerular nephritis in beagle dogs receiving a dose of 75 mg Al/kg-day of sodium aluminum phosphate. In this same study, no significant differences between exposure groups and controls were observed at the lower doses of 4 to 27 mg Al/kg-day.

A number of biochemical effects have also been reported in subchronic and chronic studies. The LOEL associated with significant effects on biochemical endpoints was 1 mgAl/kg-day as administered as aluminum maltolate in drinking water for one year (Huh *et al.*, 2005).

Reproductive/Developmental Toxicity

Canada (2010) reviewed the results of 49 studies investigating gestational, lactational and/or post-weaning exposure of rats, mice and guinea pigs to aluminum salts through diet, through drinking water or by gavage. The aluminum salts administered in these studies included chloride, nitrate, sulfate, lactate and hydroxide. In a few studies, citrate or ascorbic acid was added to enhance absorption of aluminum. The lack of information on base diet for some studies is a major source of uncertainty with respect to the potential combined dose, particularly when the administered dose was low in comparison to the possible base diet dose. There is also uncertainty associated with reported LOELs that are of the same magnitude as the reported LD_{50} for the administered salt.

The most commonly observed neurobehavioral effects in the developmental studies were decreased grip strength, reduced temperature sensitivity, reduced or delayed auditory startle responsiveness, and impaired negative geotaxis response. Decreased activity levels, locomotor coordination, as well as impaired righting reflex were also observed, although not consistently. The LOEL for these effects was 100 mg Al/kg-day, observed

in Wistar rats administered aluminum lactate in the maternal diet during gestation (Bernuzzi *et al.*, 1989), as well as in Swiss Webster mice administered aluminum lactate in the maternal diet during gestation, lactation and then in the diet of offspring throughout the lifespan (Golub *et al.*, 2000).

The observations on the effects on learning and memory of developmental exposure to aluminum salts also varied considerably. Improved performance in the maze tasks was observed in some studies, while in others impaired performance or no change was found. Developmental exposure of mice and rats to aluminum salts also produced some evidence of disturbances in brain biochemistry. The LOEL for these biochemical effects was approximately 20 mg Al/kg-day (Kim 2003). Neurodevelopmental histopathological effects have been reported at doses of 85-100 mg Al/kg-day.

In the few reproductive toxicity studies, there was reduced maternal weight gain was reported, but not in others. Some of the studies reported decreased pup body weight, while other studies reported no effects. The LOEL for reproductive parameters, including fetal growth, was 13 mg Al/kg-day (Paternain *et al.*, 1988; Domingo *et al.*, 1987), in which Sprague-Dawley rat dams received this dose via gavage as aluminum nitrate. Other observed reproductive and developmental effects included decreased number of corpora lutea and number of implantation sites as well as skeletal malformations. Colomina *et al.* (2005) reported a delay in sexual maturation in both males and females, although this effect was produced at different dose levels in the two sexes (at 50 mg Al/kg-day in females and at 100 mg Al/kg-day in males). Misawa and Shigeta (1993) observed delayed pinna detachment and eye opening in female pups.

No significant maternal or developmental toxicity, as measured by fetal weight gain, reproductive parameters or fetal malformations, was observed by McCormack *et al.* (1979) at a combined dietary dose of aluminum chloride of 50 mg Al/kg-day, nor by Gomez *et al.* (1990) where 265 mg Al/kg-day of aluminum hydroxide was administered to dams via gavage during gestation.

Human Studies

Neurotoxic effects have been reported in humans from aluminum exposure, as well as bone and blood toxicity, during medical treatment in which the gastrointestinal barrier is bypassed (*e.g.*, aluminum-induced encephalopathy through dialysis treatment in patients with renal failure). Some epidemiological evidence exists for long-term cognitive impairment in pre-term infants receiving aluminum-containing nutritional solution intravenously and also associated with occupational exposures. These exposures are not applicable to the general population, although it does support the identification of neurotoxicity and developmental neurotoxicity as endpoints of concern in the human health risk assessment for aluminum.

With respect to the conditions of exposure in the general population, the most relevant available information is provided by the epidemiological investigations into the

association between exposure to aluminum through drinking water and Alzheimer's disease (AD) and other forms of dementia. The hypothesis of aluminum in drinking water as a risk factor for AD or impaired cognitive function in the elderly is controversial in the scientific community. Recent reviews of the epidemiological literature have reiterated the limitations of the epidemiological data base, in its entirety, in regard to the causality of the occurrence of aluminum in the environment and AD, while also maintaining that the hypothesis cannot be rejected at this time (InVS-Afssa-Afssaps 2003; ATSDR 2008; JECFA 2006; Krewski *et al.*, 2007). As a result of these limitations, JECFA (2006) and ATSDR (2006) chose not to base their regulatory values for aluminum intake on epidemiological studies.

Critical Effect(s)/Basis for Screening Level Criteria

The main focus on aluminum toxicity has been on neurotoxicity and reproductive and developmental toxicity, principally because of the evidence from human case studies and epidemiological studies indicating that these effects may be of concern. Canada (2010) evaluated a total of 138 toxicological studies, published from 1979 to 2007, reporting on neurotoxicity and reproductive/developmental effects of oral aluminum exposure in rodents, monkeys and dogs. No single or limited number of studies provided an adequate basis for characterizing the dose-response relationship. Thus, the entire database was considered in determining the lower range of doses for the adverse effects on the critical endpoints of concern.

Exposure-response analysis

Two subsets of the studies, based primarily on exposure period, were evaluated: (a) neurotoxic effects in adults following subchronic or chronic exposure ($\geq$90 days); and (b) neurodevelopmental and reproductive effects in prenatal/lactation exposure studies. These subsets include studies with highly diverse experimental conditions, notably with respect to the animal species and strain, type of aluminum salt administered, exposure vehicle as well as other aspects of the experimental methodology. There is also variability in the reporting of doses. Some researchers adjust the concentration in drinking water for a constant dose in mg Al/kg bw/d and report this value, while others estimate doses in terms of mg Al/kg bw/d based on measures of animal body weight and food and water intake, but keep the same concentration in the diet throughout the experiment. In other cases, the dose is reported only as a concentration administered via diet, drinking water or gavage, and the intake in mg Al/kg bw/d has been estimated using Health Canada (1994) reference values for animal body weight and intake.

In the case of the developmental studies, the LOELs are reported as the maternal dose at the beginning of gestation. In the studies where the concentration in drinking water or the diet remained constant, this dose would generally be lower than the received dose, due to increased food and water intake during gestation and lactation. For the purpose of human health risk assessment, however, the maternal dose at the beginning of pregnancy was considered, as this provided a common point of comparison between studies.

One condition that was applied to both subsets of studies was that the experimental administered dose constitutes the principal contribution to total aluminum. As previously discussed, the concentration of aluminum in standard laboratory rodent chow may be significant. In the majority of studies, this base diet concentration is not measured. Base diet concentration would considerably impact the exposure-response analysis if: (a) the bioavailability of the aluminum contained in the chow was of a similar magnitude to the bioavailability of the administered aluminum; and (b) the lab chow were to contribute a large percentage of the total aluminum exposure. While it could be hypothesised that the aluminum in the lab chow, associated with ligands in the food matrix, would be less soluble and therefore less bioavailable than added aluminum, no experimental data were identified to assess the relative bioavailabilities of aluminum in lab chow and added aluminum salts. Therefore, with regard to those studies where base diet was not quantified, studies were included in the two subsets only if the administered dose (D_a) likely exceeded the base diet dose (i.e., $D_a > 10$ mg Al/kg-day for rats and $D_a > 30$ mg Al/kg-day for mice). This approach limits the influence of the unknown base diet aluminum concentration on the exposure-response analysis, but does introduce a bias against inclusion of low dose studies in the exposure-response analysis.

The following observations concerning the exposure-response relationship for aluminum may be made based on the studies selected for the exposure response analysis: (1) there is a wide variation in reported LOELs (from 1 to 663 mg Al/kg-day); (2) there is a predominance of single dose studies or studies where the LOEL was observed at the lowest dose; (3) for the 16 subchronic and chronic exposure studies for neurotoxicity in adults (neurobehavioral and biochemical endpoints), the LOELs range between 1 and 500 mg Al/kg-day (administered and combined doses—D_a and D_c—considered together). (4) For the 22 studies of exposure during gestation and lactation (reproductive, developmental, neurodevelopmental, histopathological and biochemical endpoints), the LOELs (D_a and D_c) vary between 2 and 663 mg Al/kg-day.

The following discussion focuses particularly on studies documenting LOELs at the lowest doses, and evaluates the findings in relation to three issues: (a) use of a low administered dose; (b) toxicological significance of different endpoints; and (c) methodological strengths and limitations and consistency of study findings.

(a) Use of a low administered dose

The lowest LOEL was observed by Huh *et al.* (2005), which reported apoptosis and the activation of the catalytic activity of monoamine oxidases A and B in the brains of Sprague-Dawley rats at a reported combined dose of 1 mg Al/kg-day. The aluminum-exposed group received aluminum maltolate in drinking water over a period of 12 months. This study reported an aluminum concentration of 11.5 ppm in the base diet. Although this is a relatively low value for laboratory chow, it does constitute an aluminum dose (0.6 mg Al/kg-day) of nearly twice that of the administered dose (0.38 mg Al/kg-day). The use of an administered dose less than the base diet dose raises the question of exposure misclassification of individual animals, as the normal variability in

intake between animals may create overlap between the two groups with respect to the dose received. This is considered to be a major limitation of this study.

In spite of the extremely low administered dose, the animals receiving aluminum maltolate were found, after one year, to have approximately four times the amount of aluminum in the brain (462 ng/g) as compared to the controls (110 ng/g). This finding suggested a comparable increase in both the fraction of aluminum absorbed into the bloodstream and/or the amount of aluminum distributed to the brain when the aluminum is administered as the maltolate salt. Recently, Zhou *et al.* (2008) found differences in aluminum oral bioavailability, which were not statistically significant, between the citrate, maltolate and fluoride salts in drinking water. The measured bioavailabilities of all the salts were low (estimated means of 0.5%, 0.61% and 0.35% for maltolate, citrate and fluoride, respectively) and approximately twice the estimated bioavailability of aluminum in food (0.1% to 0.3%) as measured with the same experimental protocol.

These findings suggest that while aluminum maltolate may be more bioavailable, the increase would not be sufficient to explain the results of Huh *et al.* (2006). In light of the uncertainty associated with the reported increased brain concentrations in the Huh *et al.* (2005) study, in addition to the methodological limitation of testing an administered dose that is less than the base diet dose, the study by Huh *et al.* (2005) was not retained for the purpose of estimating the lower range of aluminum doses at which neurological effects may be expected to occur.

Other investigations with relatively low doses over periods of 12 weeks or longer have also reported neurotoxic effects. These studies were not considered in the exposure-response analysis as the aluminum content in the laboratory chow was not reported, and thus, unlike the study by Huh *et al.* (2005), the relative contribution of the aluminum in the base diet could not be evaluated. The LOELs for these studies ranged from 0.07 to 22 mg Al/kg-day (administered dose) and were associated with a significant increase in brain aluminum levels as well as significant increases in neurobehavioral or histopathological effects.

(b) Toxicological significance of different endpoints

Considering the 16 subchronic and chronic adult exposure studies, the LOELs range between 19 and 500 mg Al/kg-day(administered and combined doses—D_a and D_c—considered together, and excluding the Huh *et al.* (2005) study). For neurobehavioral endpoints (Morris water maze performance, impaired learning in the shuttle box and motor activity), the LOELs of the seven relevant studies vary between 40 to 500 mg Al/kg-day (D_a and D_c), with four studies having LOELs at D_as of 40 to 70 mg Al/kg-day (Commissaris *et al*. 1982; Lal *et al.* 1993; Gong *et al*. 2005; Mameli *et al.* 2006). The neurobehavioral endpoints examined constitute standard elements of neurobehavioral testing and impaired performance is considered to be toxicologically significant in the experimental animal.

The biochemical effects observed in the remaining studies included alterations in

neurotransmission systems, alterations in synaptosomal membrane fluidity and increased lipid peroxidation in the brain, and were associated with LOELs varying from 19 to 420 mg Al/kg-day. These observations provide supportive evidence for neurotoxicity observed via other endpoints as well as information on mechanisms of action, but are more difficult to evaluate with respect to toxicological significance. For this reason, studies with these endpoints were given less weight in the exposure-response evaluation, in comparison to studies that include neurobehavioral endpoints.

Considering the 22 studies of exposure during gestation and lactation, the LOELs (D_a and D_c) varied between 29 and 663 mg Al/kg-day. For neurobehavioural endpoints (grip strength, auditory startle, negative geotaxis and other reflexes, maze learning and thermal sensitivity, and motor development), the LOELs (administered doses) ranged from 50 to 155 mg Al/kg-day, with the LOELs of two studies falling in the range of 50 to 60 mg Al/kg-day (Colomina *et al.* 2005; Golub and Germann 2001b).

With respect to reproductive parameters, the lowest LOEL was reported by Belles *et al.* (1999), where aluminum nitrate was administered to pregnant mice via gavage at a dose of 29 mg Al/kg-day and observed an increase in the number of early deliveries and reduced fetal body weight. Reduced birth or fetal weight was also observed by Colomina *et al.* (1992) and Sharma and Mishra (2006) at LOELs ranging between 50 and 70 mg Al/kg-day. Morphological effects in offspring were also observed in the latter two studies.

The motor, reflex and learning endpoints examined in the developmental studies as well as the reproductive parameters of fetal growth and morphological variations are all standard endpoints included in neurodevelopmental testing procedures, and considered to be toxicologically significant.

(c) Evaluation of methodology and consistency of results in studies with LOELs of <70 mg Al/kg-day.

The methodologies and findings of the abovementioned studies with LOELs of less than 70 mg Al/kg-day for neurobehavioral or reproductive/developmental endpoints were compared in order to characterize the strength of evidence for the effects observed at these dose levels.

Adult Neurobehavioral Effects

Of the four neurobehavioral studies in adults, all were carried out in rats using aluminum chloride, in drinking water (Gong *et al*. 2005; Mameli *et al*. 2006; Lal *et al.* 1993), or in the diet (Commissaris *et al.* 1982), for periods varying between 90 days and 11 months.

Several weaknesses were identified in the investigations of Commissaris *et al.* (1982) and Gong *et al.* (2005). First, exposure information in these two reports was expressed as concentrations in the food or drinking water, and no information was included on intake rates or body weight of the animals. Thus the administered doses (50 and 60 mg Al/kg-

day, respectively) were calculated on the basis of default intake and body weight values (refer to Health Canada 1994), and are therefore associated with greater uncertainty than had the doses been reported by the researchers on the basis of experimental observations. Moreover, the concentration of aluminum in the base diet was not reported in the two studies, and so the combined dose could not be calculated.

The investigations of Commissaris *et al.* (1982) and Gong *et al.* (2005) were also limited by the use of a single aluminum dose and the absence of a group receiving sodium chloride. Thus, a dose-response relationship could not be examined, and the observed effects could not be definitively attributed to the aluminum ion. It should be added that these two investigations were carried out with the primary objective of examining the influence of other test substances on aluminum toxicity—parathyroid hormone and Ginkgo biloba leaf extract, respectively—and not for the purpose of evaluating aluminum toxicity at different dose levels for different endpoints.

In the study of Lal *et al.* (1993), adult male Druckrey albino rats were exposed to an administered dose of 52 mg Al/kg-day for 180 days in drinking water. Although this dose was not reported directly in this form, information on daily water consumption and average body weight was provided, allowing for calculation of the dose based on experimental data. The investigation included a range of behavioral, biochemical and histopathological endpoints. The researchers observed reduced spontaneous motor activity and impaired learning in the shuttle box and maze tests, in addition to increased lipid peroxidation and decreased Mg^{2+} and $Na^{+}K^{+}$-ATPase activities in the brain. The aluminum concentration in different brain regions was significantly increased in the aluminum-exposed animals, but no pathological alterations were observed.

In the context of evaluating the exposure-response relationship, the study by Lal *et al.* (1993) is more informative than the Commissaris *et al.* (1982) and Gong *et al.* (2005) studies, in that the dose is more accurately reported, brain aluminum content was measured and a range of endpoints were examined, with generally consistent findings reported for the different endpoints. Its limitations include the use of a single dose, the absence of a group exposed to sodium chloride and the lack of information on the aluminum concentration in the base diet. Assuming a concentration of 250 ppm of aluminum in the laboratory chow (ATSDR 2008), the corresponding approximate aluminum dose would be 13 mg Al/kg-day, leading to an estimated combined dose for the Lal *et al.* (1993) study of 65 mg Al/kg-day.

It should be noted that NOELs for impaired learning in the maze and shuttle box tests in aluminum-exposed adults have been observed at doses of 100 and 140 mg Al/kg-day, respectively by Domingo *et al.* (1996) and VonLinstow Roloff *et al.* (2002). In the study by Domingo *et al.* (1996) the aluminum was administered to rats as Al nitrate, with added citrate, in drinking water for a period of 6.5 months. Von Linstow Roloff (2002) administered Al sulfate in drinking water to rats for a period of seven months.

Of these four studies, only Mameli *et al.* (2006) included more than one dose group, and were thereby able to establish a LOEL of 43 mg Al/kg-day and a NOEL of 22 mg Al/kg-

day. At this administered dose the researchers found impairment of the vestibulo-ocular reflex in male rats of different ages (3, 10 and 24 months old) exposed to aluminum chloride in drinking water. Significant increases of aluminum were observed in brain regions (brainstem-cerebellum and cerebrum). This study, which used 20 animals per dose per age group, also included an exposure group for the salt, in this case sodium chloride, such that the observed effects could be more clearly attributed to the aluminum and not the chloride ion. It should be noted, however, that evidence from other studies supporting the effects of aluminum on the vestibulo-ocular reflex is not available, as this endpoint has not been evaluated by other researchers.

In the study by Mameli *et al.* (2006), the base diet aluminum concentration was measured but not clearly reported, nor was food intake measured. The LOEL of 43 mg Al/kg-day is thus the administered dose. The combined dose may be estimated at approximately 50 mg Al/kg-day, based on default values for rat dietary intake.

Considering the observations of LOELs and NOELs associated with neurobehavioral effects in adults as well as the probable combined doses, alterations in learning and reflexes may be observed at approximately 50 to 65 mg Al/kg-day, based on the LOELs of Mameli *et al*. (2006) and Lal *et al.* (1993) expressed as estimated combined dose.

Reproductive Effects

The lowest LOEL presented is from the study by Belles *et al.* (1999). Mice were exposed to aluminum nitrate via gavage from gestational day 6 to 15 at a dose of 29 mg Al/kg-day. In addition to the control group, one group received sodium nitrate at a similar nitrate dose. A high mortality (52%) in the aluminum-exposed pregnant mice was observed in this study, which was not observed in other developmental studies in which aluminum nitrate or other aluminum salts were administered at similar or greater doses. Other observations included reduced body weight gain in the dams during gestation and reduced fetal body weight. The number of early deliveries was also increased in the aluminum-exposed animals as compared to the control group, but there was no significant difference in this regard when compared to the sodium nitrate-exposed group. This study is limited to a single dose, and the aluminum content in the base diet was not measured. The lack of information on base diet is particularly important in studies with mice because of their small body weight. A laboratory chow containing 250 ppm of aluminum would be equivalent to a dose of approximately 33 mg Al/kg-day, which is higher than the administered dose in this investigation.

Reduced maternal body weight gain and reduced fetal weight in aluminum-exposed animals were also observed at the LOELs associated with the Sharma and Mishra (2006) and Colomina *et al.* (1992) studies. A significant reduction in pup weight was also observed at the higher doses tested in the studies of Golub and Germann (2001b) and Colomina et al. (2005), at approximately 100 mg Al/kg-day.

In the study by Sharma and Mishra (2006), rats received 70 mg Al/kg-day as aluminum chloride via gavage during gestation and lactation. In addition to the effects on fetal

weight, the authors observed an increase in skeletal malformations and in oxidative stress in the brains of mothers, fetuses and sucklings. The dose level in this study is based on the measured maternal weights. However, no information on base diet was included. The combined dose, based on a concentration of 250 ppm of aluminum in a typical lab chow and default values of Health Canada (1994), is estimated at approximately 83 mg Al/kg-day.

Colomina *et al.* (1992) administered aluminum lactate to mice through gavage. A LOEL of 57.5 mg Al/kg-day (administered dose) was observed for an increased incidence of morphological effects (cleft palate, delayed ossification of parietals), in addition to reduced fetal weight. This study did not report the aluminum content in the base diet. Considering the reported concentration in the laboratory chow used by this research group in other experiments of 42 ppm of aluminum, the estimated base diet dose would be approximately 5.5 mg Al/kg-day, based on Health Canada (1994) default values for body weight and food intake in mice. The combined dose would then be estimated at 63 mg Al/kg-day.

In contrast to the findings mentioned above, in the study of McCormack *et al.* (1979), rats were fed aluminum chloride in the diet at maternal dose levels of 25 and 50 mg Al/kg-day during gestation, and no differences in fetal growth or skeletal anomalies were observed. Colomina *et al.* (1994) found no differences in dam body weight, fetal growth or morphological variations in mice exposed via gavage to 104 mg Al/kg-day of aluminum hydroxide, during gestation. The latter finding may have resulted from the lower solubility and therefore the lower bioavailability of the hydroxide salt.
Considering the observations of LOELs and NOELs associated with reproductive effects, and the probable combined doses, reductions in fetal and pup body weight may be observed beginning at approximately 60 mg Al/kg-day (e.g., Colomina *et al.* (1992)). The study of Belles *et al.* (1999), in which a LOEL of 29 mg Al/kg-day was observed for reduced fetal weight, is given less weight in this evaluation, in light of the uncertainty associated with the high maternal mortality rate observed in the exposed animals, and the elevated contribution of the base diet to aluminum exposure as compared to the administered dose.

Neurodevelopmental Effects

The lowest LOELs are from the studies of Colomina *et al.* (2005) and Golub and Germann (2001b). Both of these studies included exposure through gestation and lactation. The experimental conditions of the two studies, however, differed in many other respects, and these are described briefly below.

Colomina *et al.* (2005) exposed female Sprague-Dawley rats to 0, 50, or 100 mg Al/kg-day as aluminum nitrate in drinking water with citric acids, in combination with a base diet dose of approximately 3 mg Al/kg-day. Aluminum exposure was maintained through gestation, lactation and the life of the dams. The maternal effects of aluminum administration included decreased food intake (with reduced body weight) during gestation and lactation and decreased water intake during lactation in the 100 mg Al/kg-

day dose group. No effects were observed with respect to the length of gestation, the number of litters or the number of fetuses per litter. With respect to the pups, there was a significant increase in the number of days until sexual maturation in males in the 100 mg Al/kg-day dose group and in females at both 50 and 100 mg Al/kg-day. A significant reduction in forelimb grip strength in males was observed in the 100 mg Al/kg-day dose group on PND 11 compared controls. In the water maze task, assessing spatial learning, the performance of aluminum treated rats (50 mg Al/kg-day) was significantly improved in comparison to the control group. The pups in the 100 mg Al/kg-day dose group were not tested in the water maze test, because of altered maternal food and water intakes in this group. No differences in aluminum-exposed animals were observed with respect to surface righting, negative geotaxis or activity in an open field. The authors also measured aluminum concentration in brain regions but did not find increased levels in any regions in the aluminum-exposed animals.

Golub and Germann (2001b) investigated the long-term consequences of prenatal exposures to aluminum in Swiss Webster mice, in conjunction with a suboptimal base diet. The base diet was designed to simulate the usual diet of young women in the U.S., with respect to estimated phosphate, calcium, iron, magnesium, and zinc intakes. Following breeding, dams were exposed to aluminum in the diet as aluminum lactate. The doses were equivalent to approximately < 1, 10, 50 and 100 mg Al/kg-day, as estimated at the beginning of gestation. The dams were exposed throughout gestation and lactation. Following weaning at 21 days, the pups were fed the same diet as the dams for two weeks (although the per kg dose levels were higher). No effects were observed in the number of dams completing pregnancy, gestation length, weight gain of the dams (GD0 to GD15), litter size or birth weight. By weaning, both males and females in the two highest dose groups weighed significantly less than the controls, although by PND35 only the highest dose group showed this effect. The female offspring of the highest dose group (maternal exposure of 100 mg Al/kg-day) were found to be slower in maze learning at three months old, as indicated by longer latencies during the first three sessions of the four-session learning series. All aluminum treated groups were similar to controls by the fourth session. Differences in aluminum exposed groups were also observed in the cue relocation trials, in which average trial latency was significantly increased at the two highest dose levels (50 and 100 mg Al/kg-day) as compared to the control group. In the motor testing of male offspring at five months old, males in the highest dose group (maternal exposure of 100 mg Al/kg-day) had significantly lower hindlimb grip strength and greater number of rotations in the rotarod test (animal losing footing). When body weight was taken into account, only the findings for the rotarod test remained significant.

The investigations by Colomina *et al.* (2005) and Golub and Germann (2001b) are methodologically superior in many respects to the majority of the studies. Both include two dose levels in addition to the control group, quantify the aluminum dose associated with the base diet, and examine a range of reproductive and neurodevelopmental endpoints. The Colomina *et al.* (2005) study includes measurement of aluminum concentration in different brain regions. The Golub and Germann (2001b) study, however, used an experimental protocol designed to test the influence of a suboptimal

diet, which limits comparisons of the findings with other investigations of aluminum toxicity, particularly as no groups were included with equivalent aluminum dose levels and a standard diet.

Interpretation of cognitive and motor test findings in the studies investigating the effects of aluminum exposure is also complicated by a possible biphasic dose-response relationship. For example, in the study by Roig *et al.* (2006), rats received aluminum nitrate in drinking water during gestation and lactation at administered doses of 50 and 100 mg Al/kg-day. No difference in the motor activity of aluminum-exposed pups and controls was found. However, the animals exposed to 50 mg Al/kg-day showed an improved performance in maze learning. The performance of animals exposed to 100mgAl/kg-day was significantly reduced as compared to the animals exposed to 50 mg Al/kg-day, but not significantly different from controls. Colomina *et al.* (2005) also observed improved maze performance in aluminum-exposed animals, although the highest exposure group in that study was not tested for this endpoint.
Considering the neurodevelopmental studies described above, diminished performance in learning or motor tests may be observed in animals exposed prenatally or through lactation at maternal combined doses beginning at approximately 50 mg Al/kg-day. There is, however, considerable variability in various study results with respect to these endpoints, which also suggest a possible biphasic dose-response relationship in relation to maze learning.

Conclusion

A dose of 50 mg Al/kg-day, expressed as a combined dose of total aluminum, was considered the level at which neurological and reproductive/developmental effects begin to be repeatedly observed in animal studies. While 50 mg Al/kg-day is an estimation of the lower end of a broad range of LOELs observed under different experimental conditions, it is not considered to be an overly conservative estimate of the effect level of concern. There are two sources of bias against consideration of lower values of LOEL in the above characterization: (a) low-dose studies were not considered if the administered dose was less than the probable base diet dose; and (b) LOELs from single-dose studies may be overestimates of the actual effect levels. Thus, 50 mg Al/kg-day has, however, produced neurotoxic, reproductive and developmental effects in laboratory animals more consistently under a wide range of experimental conditions, as compared to lower doses. This exposure level is therefore retained for the purpose of the characterization of human health risks as the level of concern for neurotoxic, neurodevelopmental and reproductive effects.

LOEL [Al] = 50 mg/kg/day

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (LOEL to NOAEL)

Oral RfD [Al] = 50/1,000 = 0.05 mg/kg/day

Drinking water guideline value [Al] = 0.18 ppm

Australian drinking water guideline [sulfate] = 500 ppm (health); 250 ppm (aesthetic)

Toxicity Profile

Cellulase
(CAS No. 9012-54-8)

Enzymes are catalytic proteins or polypeptides and consist of amino acid residues coupled via peptide bonds. They are primarily characterized by their biocatalytic or enzymatic activity. There is a broad range of detergent cellulases used both from fungal as well as from bacterial origin; all are characterized by ß-1,4-endoglucanase activity.

Acute Toxicity

The oral LD_{50} of a cellulase enzyme was determined to be 8,000 mg/kg for mice and >10,000 mg/kg for rats (HERA, 2005). The inhalation LC_{50} of the same enzyme in rats is >3.48 mg/L, with a mass mean diameter of 7.8 µm and a geometric standard deviation of 2.1 µm (HERA, 2005).

Irritation

Cellulase enzymes are mild to non-irritating to the skin and eyes of rabbits (HERA, 2005). The amount of protease contamination in the enzyme test preparation, however, may affect the irritation potential, particularly with regards to eye irritation.

Sensitization

A cellulase enzyme was not a skin sensitizer to guinea pigs (HERA, 2005).

Repeated Dose Toxicity

Male and female rats were dosed by oral gavage with 0, 300, 1,000 or 3,000 mg/kg of a cellulase enzyme for 4 weeks. There were no treatment-related clinical signs, but a slight dose-related increase in body weight gain (approx. 7%) was seen in the males. No treatment-related changes were noted in the hematology or clinical chemistry. There were no gross or histopathologic changes that were considered treatment-related (HERA, 2005).

Male and female rats were given in their feed concentrations of 0, 120, 600 or 3,000 mg/kg of this enzyme for 13 weeks. There were no treatment-related clinical signs. A reduction in body weight gain was seen in both sexes at the 3,000 mg/kg level (10% in males and 20% in females). A slight reduction in food consumption was also noted for the 3,000 mg/kg dose group. Serum alkaline phosphatase activity was increased in the 600 and 3,000 mg/kg females in a dose-dependent manner. However, there were no organ

weight changes and no effects seen in the gross or histopathologic examination that were considered treatment-related. The NOAEL for this study is considered to be 600 mg/kg/day (HERA, 2005).

Genotoxicity

In an *in vitro* bacterial mutation assay, a cellulase enzyme was not mutagenic to *Salmonella typhimurium* strains TA 1535, TA 100, TA 1537 and TA98 in the presence or absence of metabolic activation. In an *in vivo* bone marrow micronucleus assay, a cellulase enzyme was not genotoxic when given to rats by oral gavage (HERA, 2005).

Carcinogenicity

No data were found.

Reproductive Toxicity

No data were found.

Developmental Toxicity

No data were found.

Key Study/Critical Effect for Screening Criteria

In a 13-week dietary study, there was reduced body weight gain in rats given 3,000 mg/kg of this enzyme. Although there was a dose-related increase in serum alkaline phosphatase activity, there were no significant changes to liver weights, nor were there any accompanying gross or histopathologic changes in the liver. Thus, the changes in serum alkaline phosphatase activity were not considered an adverse effect and the NOAEL for this study is 600 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral Reference Dose = 600/1,000 = 0.6 mg/kg/day

Drinking water guideline value = 2.1 ppm

Toxicity Profile

Lactose
(CAS No. 63-42-3)

Lactose is a disaccharide sugar composed of galactose and glucose. It is naturally synthesized in the mammary gland of virtually all mammals, occurring in milk at levels between 1 and 7%. Commercially, lactose is extracted from the whey of cow's milk (whey is the residual liquid of milk following cheese and casein production) and is purified extensively to remove fats, proteins, vitamins and minerals (Baldrick and Bamford, 1997; Goodhart, 1994).

Pharmacokinetics/Metabolism

Lactose *per se* is not readily absorbed by the oral route. After dietary intake, lactose is readily hydrolyzed to galactose and glucose by the enzyme lactase (Hansen, 1974; Williams, 1986). Lactase is a β-galactosidase found in the brush border of the intestinal epithelium. Once hydrolyzed, the monosaccharides are then readily absorbed. Lactose can also be hydrolyzed by other enzymes, such as acid β-galactosidase.

Acute Toxicity

The acute oral LD_{50} in rats is >10,000 mg/kg (Baldrick and Bamford, 1997).

Irritation

No data were located.

Sensitization

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Wistar rats were fed 20% lactose for 12 weeks before mating, and during pregnancy and lactation. At weaning, the animals were fed the same diet and the study was terminated at week 130. There were low body weights; increased blood alkaline phosphatase and urinary calcium; decreased pH of cecum contents; enlargement/increased weight of the cecum; pelvic nephrocalcinosis of the kidneys; increased proliferation of the bile ducts; adrenal medullary hyperplasia and pheochromocytomas; and Leydig cell tumors (Sinkeldam *et al.*, 1992a).

Similar findings were also observed in another study in which rats were fed 20% lactose in their diet for 130 weeks. Findings included loose feces (week one and two only); decreased pH of the feces; low body weights; increased food and water consumption; increased blood alkaline phosphatase and decreased bicarbonate; increased calcium concentration and excretion; reduced urinary pH; increased cecum weight; mineralization of the renal pelvis; increased incidence of basophilic cell foci in the adrenal medulla; and Leydig cell hyperplasia (De Groot *et al.*, 1995).

Genotoxicity

Lactose was negative in an *in vitro* chromosomal aberration study with cultured human lymphocytes in the presence and absence of metabolic activation (Sinkeldam *et al.*, 1992a).

Reproductive/Developmental Toxicity

In a multi-generation study, rats were fed 20% lactose over three successive generations. There were no adverse effects on fertility or reproductive performance. There was a slight decrease in the number of pups born alive, litter size at birth, viability index and pup weight for F_0 and F_1 offspring. There were signs of low body weights in the parental animals, and enlargement and increased weight of the cecum (Sinkeldam *et al.*, 1992b).

Pregnant mice were given 10,000 mg/kg lactose during gestation days 8-12. No maternal toxicity was observed and there were no effects on litter size, body weight on days 1 and 3, or neonate survival (Seidenberg *et al.*, 1986).

Key Study/Critical Effect for Screening Criteria

Many of the findings from the oral studies on lactose can be related to the fact that it is poorly absorbed from the small intestine. This results in a large proportion reaching the cecum and colon where it is readily fermented by the intestinal microflora. Consequently, there is increased production of volatile fatty acids and lactic acid, and a lowering of the pH and increased osmotic pressure. These changes facilitate calcium absorption. The adrenal tumors are thought to be secondary to increased calcium absorption from the intestine. Increased Leydig cell tumors in rats are of questionable relevance to humans.

Adverse effects were noted in rats given 20% in their diet for 130 weeks. Since there was only one dose level, a NOAEL was not identified.

LOAEL (mg/kg/day) = 20,000 ppm * 0.05 = 1,000 mg/kg/day

Where 0.05 is the fraction of body weight that is consumed per day as food for the mouse (U.S. EPA).

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (LOAEL to NOAEL)

Oral Reference Dose = 1,000/1,000 = 1.0 mg/kg/day

Drinking water guideline value = 3.5 ppm

Toxicity Profile

Maltodextrin
(CAS No. 9050-36-6)

Maltodextrin is a nonsweet nutritive saccharide polymer that consists of D-glucose unites linked primarily by $\alpha,1\rightarrow4$ bonds and that has a dextrose equivalent (D.E.) of <20. Typical commercial maltodextrins contain as few as three and as many as nineteen linked dextrose units. It is prepared as a white powder or concentrated solution by partial hydrolysis of corn starch, potato starch, or rice starch with safe and suitable acids and enzymes.

Maltodextrin is considered to be a biopolymer that is broken down in the gastrointestinal tract to its monomeric units and absorbed. The corresponding monomers are found naturally in the body. Thus, maltodextrin is expected to be safe to human health.

The U.S. FDA lists maltodextrin as GRAS (Generally Recognized as Safe).

No toxicity data could be found on maltodextrin and therefore no oral reference dose or drinking water standard was determined.

http://www.sugar.org/other-sweeteners/other-caloric-sweeteners.html#maltodextrin

Toxicity Profile

Potassium chloride
(CAS No. 7447-40-7)

Potassium chloride (KCl) has been reviewed in the OECD-SIDS program (OECD, 2001).

Potassium chloride (KCl) is an inorganic salt that readily dissociates in aqueous media to K^+ and Cl^-.

Acute Toxicity

The oral LD_{50} in rats has been reported to be 3,020 mg/kg (Boyd and Shanas, 1961).

Irritation

Potassium chloride did not produce an irritant response in an *in vitro* skin irritation OECD 439 test or an *in vitro* eye irritation test (ECHA).

Repeated Dose Toxicity

Fourteen female rats were given KCl in their drinking water (approximately 5,250 mg/kg/day) for 105 days. Ten rats were sacrificed after 105 days of exposure for examination of the heart, kidneys and the adrenals; four rats (recovery group) were kept for an additional month. KCl exposure resulted in decreased heart weight, increased kidney weight, and enlargement of part of the adrenals. All changes were reversible within one month of exposure (Bacchus, 1951).

F344/Slc male rats were given 0, 110, 450 or 1,820 mg/kg/day KCl in feed for two years. At the end of the study, survival rates were 48%, 64%, 58% and 84% in the controls, 110, 45 and 1,820 mg/kg/day groups. Nephritis was reported to be predominant in all groups, including the controls. The only treatment-related effect observed was gastritis (inflammation of the stomach lining). The incidence of gastritis and ulcers were 6%, 18%, 18% and 30% in the controls, 110, 450 and 1,820 mg/kg/day groups (Imai *et al.*, 1968).

Male and female Wistar rats were fed diets containing 0 or 3% KCl over a total period of 30 months: Examination after 13 weeks (10 rats/sex/group), after 18 months (15 rats/sex/group) and after 30 months (50 rats/sex /group). Due to the reduction of feed intake the mean test substance intake and mean body weight decreased in time. After 30 months of treatment, there was hypertrophy of the zona glomerulosa in the adrenals (24/50 treated rats versus 4/50 in controls); and cystitis in the urinary bladder (males: 3/59; females 3/50) and single epithelial hyperplasia of the bladder (males 3/50; females

2/50) (Lina *et al.*, 1994; Lina and Kuijpers, 2004)**.**

Genotoxicity

Potassium chloride was not mutagenic to *Salmonella typhimurium* strains TA100, TA 1535, TA 1537 and TA 98 strains in an *in vitro* bacterial mutation assay in the presence or absence of metabolic activation (Mortelmans *et al.*, 1986). KCl was also not mutagenic to *E. coli* in a SOS chromotest (Olivier and Marzin, 1987).

In two different studies, KCl was found to be weakly mutagenic to mouse lymphoma L5178Y cells at high concentrations (Myhr and Caspary, 1988; Mitchell *et al.*, 1988).

Potassium chloride induced a significant increase in chromosomal aberrations in Chinese Hamster lung fibroblasts (V79) cells only at the highest test dose (12,000 µg/ml) in the absence of a metabolic activation system. Measurements of the osmotic pressure of the medium revealed a two-fold increase at this test compound concentration when compared to the normal medium (530 mOsmol/ kg versus 253 mOsmol/kg (Hasegawa *et al.*, 1984). There are two other reports on the effect of KCl on formation of chromosome aberrations in Chinese hamster ovary cells (CHO). In these studies KCl concentrations of 75 and 80 mM (approximately 5500 and 6000 µg/ml) resulted in 19% and 28% aberrant cells respectively. Increased number of chromosome aberrations was observed with KCl concentrations that reduced cell survival 40% and more. It is reasonable to conclude that the increases in mutagenicity and chromosome aberrations observed in these studies are related to cytotoxicity resulting from the high KCl concentrations used. This argument is supported by the studies on the effect of increased osmolarity on genotoxicity in cultured mammalian cells.

The reported mutagenic effect of KCl most probably results from a disruption of osmotic balance of cells with a subsequent interference with chromosomal stability. This may result in the clastogenic effects (DNA breakage and chromosome structural instability) due to K^+ effects on sequestering of Mg^{++} ions required for normal maintenance of chromatin integrity. Other chemicals may also exert such effect (*e.g.*, NaCl, sucrose).

Carcinogenicity

F344/Slc male rats were given 0, 110, 450 or 1,820 mg/kg/day KCl in feed for two years. At the end of the study, survival rates were 48%, 64%, 58% and 84% in the controls, 110, 45 and 1,820 mg/kg/day groups. There was no increased incidence of tumors that were considered to be treatment-related (Imai *et al.*, 1968).

Reproductive/Developmental Toxicity

Pregnant female Wistar rats were given by oral gavage 3.1 to 310 mg/kg KCl during gestation days 5 through 15, and sacrificed on gestation day 20. There were no effects on

survival, total number of corpora lutea, implant sites, resorptions, soft tissue observations (urogenital tract), or live offspring. No treatment-related effects were seen in the offspring with regards to survival, sex ratio, average offspring weight, external congenital abnormalities, soft tissue or skeletal defects. The maternal and developmental NOAELs were 310 mg/kg/day (FDRL, 1975).

Female CD-1 mice were given by oral gavage 2.35 to 235 mg/kg KCL during gestation days 5 through 15, and sacrificed on gestation day 17. There were no effects on survival, total number of corpora lutea, implant sites, resorptions, soft tissue observations (urogenital tract), or live offspring. No treatment-related effects were seen in the offspring with regards to survival, sex ratio, average offspring weight, external congenital abnormalities, soft tissue or skeletal defects. The maternal and developmental NOAELs were 235 mg/kg/day (FDRL, 1975).

Key Study/Critical Effect for Screening Criteria

In a two-year rat feeding study, there was an increased incidence of gastritis and ulcers at dose levels of $\geq$110 mg/kg/day (Imai *et al.*, 1968). There was no NOAEL. Thus, the LOAEL for this study is 110 mg/kgday. Since the gastritis and ulcers are the result of a localized irritation effect of the test substance (site of contact) in the gastrointestinal tract, an uncertainty factor for interspecies variability is deemed unnecessary.

For systemic effects, the NOAEL for the two-year rat feeding study is considered to be 1,820 mg/kg/day, the highest dose tested.

Uncertainty factors: 10 (intraspecies variability); 10 (interspecies variability); 1 (intraspecies variability)

Oral Reference Dose = 1,820/100 = 18.2 mg/kg/day

Drinking water guideline: 64 ppm

Toxicity Profile

Shellac, Ammonium salt
(CAS No. 68308-35-8)

Lac is the hardened resinous secretion of the insesct *Kerria lacca* (Douglas, 1971; CIR, 1986). The secreted lac or sticklac contains lac resin, erythrolaccin, wax, inset debris, wood materials, sand, dust and water-soluble impurities. The semirefined seedlac of commerce is the yellowish granular material obtained from the processing of sticklac (Douglas, 1971; Misra and Sengupta, 1970; CIR, 1986).

Unrefined shellac can contain shellac wax and erythrolaccin (the yellow material), which both comprise about 6% of Shellac (CIR, 1986). The removal of these constituents yields lac resin that has a soft (30%) and hard (70%) components (CIR, 1986). Mild alkaline hydrolysis of this resin results in a complex mixture of hydroxyaliphatic and alicyclic acids and their polyesters. The composition of the mixture varies with the lac source and the time of collection (CIR, 1986).

The major component of the aliphatic fraction is aleuritic acid. The alicyclic fraction consists of sesquiterpenic acids, primarily jalaric acid and its derivatives. The native form of the pure lac resin molecule has a molecular weight of 2,095, which contains four terpene acids (mostly jalaric acid) and four aleuritic acid units in repeating ester linkage (Singh *et al.*, 1974). The proposed structure for lac resin respresents an average situation since the molecule may not always be homogenous with respect to sequence or ratio of jalaric acid to other sesquiterpenic acid substitutes (Singh *et al.*, 1974). The sesquiterpenic acids in lac resin are jalaric acid, shellolic acid, epishellolic acid, laksholic acid, and epilaksholic acid.

Aqueous shellac solutions can be prepared by neutralization with ethanolamines, alkalies, or borax (CIR, 1986).

Acute Toxicity

The acute oral LD_{50} in rats is >5,000 mg/kg (CIR, 1986).

Irritation

No data were located.

Sensitization

No data were located.

Repeated Dose Toxicity

Male and female Sprague-Dawley rats were fed 0, 1,000, 3,000 or 10,000 ppm Regular Bleached Shellac in commercial feed for 28 days. The rats were then mated, and a single litter (F_1) was delivered. Twenty-five weaned F_1 animals from each group were then fed with the same F_0 diets for an additional 90 days. There was no evidence of treatment-related effects in either generation, including fertility, reproductive performance, and pup development. The NOAEL for this study is 10,000 ppm (CIR, 1986).

Genotoxicity

Shellac and shellac wax were not mutgenic to *Salmonella typhimurium* strains TA1535, TA1537, TA1538, TA98, TA100 with and without metabolic activation (CIR, 1986). Shellac wax was not mutagenic to S. typhimurium strains TA1535, TA1537 and TA1538, or to *Saccharomyces cerevisiae* strain D4 with or without metabolic activation (CIR, 1986).

Carcinogenicity

No studies could be found.

Reproductive/developmental Toxicity

See Repeated Dose Toxicity section.

Key Study/Critical Effect for Screening Criteria

No treatment-related effects were noted in an one-generation rat reproductive toxicity study in which rat were fed shellac in the diet at concentrations up to 1% (10,000 ppm).

NOAEL (mg/kg/day) = 10,000 ppm * 0.05 = 500 mg/kg/day

Where 0.05 is the fraction of body weight that is consumed per day as food for the rat (U.S. EPA).

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral Reference Dose = 500/1,000 = 0.5 mg/kg/day

Drinking water guideline value = 1.75 ppm (shellac, ammonium salt may be insoluble environmental pH)

Toxicity Profile

Sodium Carboxymethyl Cellulose
(CAS No. 9004-32-4)

Sodium carboxycellulose is the sodium salt of carboxymethylcellulose. Carboxymethyl cellulose is a cellulose derivative with carboxymethyl groups (-CH_2COOH) bound to some of the hydroxyl groups of the glucopyranose monomers that make up the cellulose backbone.

Sodium carboxycellulase is a listed as GRAS (Generally Regarded as Safe) by the U.S. Food and Drug Administration (FDA GRAS database).

It is an approved food additive in the EU (EC, 1995) and may be added to all foodstuffs following *quantum satis* principle, except in products for the dietary management of metabolic disorders, where the limit of use is 10 g/L or kg (EC, 1999).

The Joint FAO/WHO Expert Committee on Food Additives has determined an Acceptable Daily Intake (ADI) for sodium carboxymethyl cellulose of "Not Specified" (no upper limit) (JECFA, 1989).

Toxicity Profile

Sodium Lauryl Sulfate
(CAS No. 151-21-3)

Sodium lauryl sulfate has been reviewed in the OECD-SIDS program (OECD, 2007a,b).

Acute Toxicity

The acute oral LD_{50} for sodium lauryl sulfate in rats was reported to be 1,200 mg/kg (Henkel KGaA, 1983). The acute dermal LD_{50} of a 33% solution of sodium lauryl sulfate was reported to be 600 mg/kg; this corresponds to 200 mg active substance/kg (Carson and Oser, 1964).

Irritation

A 25% solution of sodium lauryl sulfate was severely irritating to the skin of rabbits when applied for 4 hours under occlusive conditions (Henkel KGaA, 1987a). A 5% solution of sodium lauryl sulfate was moderately to strongly irritating to the skin of rabbits when applied for 4 hours under semi-occlusive conditions (Unilever Research, 1982). In a human repeated 4-hour patch test, a 20% solution of sodium lauryl sulfate was considered moderately irritating to the skin (Proctor and Gamble, 1998). Sodium lauryl sulfate, as a 25% solution, was severely irritating to the eyes of rabbits (Henkel KGaA, 1987b).

Sensitization

Sodium lauryl sulfate has tested positive in two out of three mouse local lymph node assays or LLNAs (Ikarashi *et al.*, 1993; Basketter *et al.*, 1994; Montelius *et al.*, 1994). The positive response in the LLNA is thought to be due to a mechanism associated with the irritation potential of sodium lauryl sulfate and not due to an allergic response (Montelius *et al.*, 1994; Basketter et al., 1994, 2002). Ammonium lauryl sulfate did not show any allergic response in a human repeat insult patch test (OECD, 2007a,b), and other structurally related alkyl sulfates also tested negative in human repeat insult patch tests (OECD, 2007a,b). There have been a few reported contact sensitization cases seen under conditions where also other, possibly sensitizing agents were used or on compromised skin (OECD, 2007a,b).

Repeated Dose Toxicity

Male and female rats were given 0, 40, 200, 1,000 or 5,000 ppm (corresponding to 3, 17, 86 or 430 mg/kg-day) sodium lauryl sulfate in their feed for 90 days. There were

increased liver weights in the high-dose females animals; no other adverse effects were observed. The NOAEL for this study is 1,000 ppm (86 mg/kg/day) (Walker *et al.*, 1967).

Male and female rats were given by oral gavage 0, 30, 100 or 300/600 mg/kg of a 90% aqueous solution of sodium lauryl sulfate for 28 days. The high-dose of 300 mg/kg was changed to 600 mg/kg after 10 days of treatment. At the high-dose, feed intake and body weight were reduced, and water intake was increased. There was bleeding and ulceration of the stomach, and transient alterations of the tongue and myocard. Hematological findings included increased leucocytes and alanine aminotransferase (ALT) activity; and decreased hematocrit and erythrocyte volume (MCV). Relative weights of adrenals, kidneys, brain, gonads and liver were increased; the relative thymus weight was decreased. There were no effects at the 100 mg/kg dose level . The NOAEL for this study is 90 mg/kg/day (90% of the 100 mg/kg dose level) (Henkel KGaA, 1987c).

A sodium $C_{12\text{-}15}$ alkyl sulfate was investigated in 13-week rat dietary study. The dietary concentrations were 0, 0, 0.07, 0.14, 0.28, 0.56, 1.13 or 2.25% (0, 58, 1134, 228, 470, 961, or 1,944 mg/kg/day for males; 0, 66, 131, 261, 506, 1,070 or 2,218 mg/kg/day for females). The LOAEL for this study was 0.28% (245 mg/kg/day) based on hypertrophy of the liver, and the NOAEL was 0.14% (122 mg/kg/day) (Unilever Research, 1976d).

In two separate studies, male and female Wistar rats were given 0, 0.015, 0.15 or 1.5% sodium $C_{12\text{-}15}$ alkyl sulfate in their diet (approximately 0, 11, 113 or 1,125 mg/kg/day) for two years. The findings in both studies were very similar. The survival rate in the high-dose animals for both studies was about 70%. Animals dosed with 1.5% showed decreased growth rates, with also decreases in food and water intake. In the high-dose animals, there was increased absolute and relative liver weights, changes in serum liver enzymes, hypertrophy of the liver parenchyma, and a decrease in the incidence and severity of chronic nephropathy and nephrocalcinosis. The NOAEL for these two studies were considered to be 113 mg/kg/day (Unilever Research, 1995a,b).

Genotoxicity

Sodium lauryl sulfate was not genotoxic in a variety of *in vitro* and *in vivo* genotoxicity tests (OECD, 2007a,b).

Carcinogenicity

In two separate studies, male and female Wistar rats were given 0, 0.015, 0.15 or 1.5% sodium $C_{12\text{-}15}$ alkyl sulfate in their diet (approximately 0, 11, 113 or 1,125 mg/kg/day) for two years. The findings in both studies were very similar. The survival rate in the high-dose animals for both studies was about 70%. There were no increased incidence of tumors that were considered treatment-related (Unilever Research, 1995a,b).

Reproductive Toxicity

In a dominant lethal study, male Swiss albino mice were fed either 1 % sodium lauryl sulfate for 2 weeks or with 0.1 % sodium lauryl sulfate for 6 weeks. Body weights were significantly decreased at the 1% dose level, while the treatment caused no adverse effects on fertility (*i.e.*, impairment of epididymal spermatozoa) (Hemsworth *et al.*, 1981). In the 13-week oral toxicity study with sodium C_{12-15} alkyl sulfates (CAS No. 68890-70-0), there were no indications of adverse effects on the reproductive organs. (Unilever Research, 1976).

Developmental Toxicity

Pregnant female rats were dosed by oral gavage with 0, 0.2, 2, 300 or 600 mg/kg sodium lauryl sulfate during gestational days 6-15. Mortality (3/20 dams) occurred at 600 mg/kg. There was slight to moderate maternal toxicity at >300 mg/kg. No developmental toxicity was noted at any dose level. The maternal and developmental NOAELs were 2 and 600 mg/kg/day, respectively (Palmer *et al.*, 1975).

Pregnant female mice were dosed by oral gavage with 0, 0.2, 2, 300 or 600 mg/kg sodium lauryl sulfate during gestational days 6-15. There were 4/20 maternal deaths at 600 mg/kg, and 1/20 maternal deaths at 300 mg/kg. At 600 mg/kg, there was total resorption and/or increased incidence of litter loss. At <300 mg/kg, there were no adverse effects on fetal morphogenesis. The maternal and developmental NOAELS were 2 and 300 mg/kg/day, respectively (Palmer *et al.*, 1975).

Pregnant female rabbits were dosed by oral gavage with 0, 0.2, 2, 300 or 600 mg/kg sodium lauryl sulfate during gestational days 6-18. There were 11/13 maternal deaths at 600 mg/kg, and 1/13 maternal deaths at 300 mg/kg. Maternal toxicity at 300 mg/kg included diarrhea, anorexia, weight loss, cachexia, and fetal loss. Developmental effects were seen at 600 mg/kg and included abortion, total resorption and/or increased incidence of litter loss. At 300 mg/kg, there were no adverse effects on fetal morphogenesis. The maternal and developmental NOAELs are 2 and 300 mg/kg/day, respectively Palmer *et al.*, 1975).

Key Study/Critical Effect for Screening Criteria

Two chronic rat dietary studies were conducted on sodium lauryl sulfate. The LOAEL for these two studies was 1,125 mg/kg/day based on liver effects. The NOAELs were considered to be 113 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral Reference Dose = 113/100 = 1.1 mg/kg/day

Drinking water guideline value = 4 ppm

Toxicity Profile

Sorbitan, monododecanoate poly(oxy-1,2-diethanediyl)
(CAS No. 9005-64-5)

Sorbitan, monododecanoate poly(oxy-1,2-diethanediyl) or PEG sorbitan monolaurate is a hydrophilic, nonionic surfactant that is also called Polysorbate 20. It has been approved by the U.S. FDA as a direct and indirect food additive for human consumption with certain restrictions.

Metabolism

The metabolism of radiolabeled polysorbates has been studied in rats. After oral administration, the ester linkage of the polysorbate molecule is hydrolyzed by pancreatic lipase and the released fatty acid is absorbed and metabolized. Essentially all of the fatty acid in polysorbate 80 fed as 10% of the diet is hydrolyzed and absorbed (Oser and Oser, 1957). In another study, the labeled lauric acid moiety of polysorbate 20 was rapidly absorbed and oxidized by rats (Treon *et al.*, 1967). After 24 hours, about 75% of the lauric acid was oxidized and expired as CO_2; 4% was not absorbed from the gastrointestinal tract. The approximate distribution of radioactivity 24 hours after oral administration of polysorbate 20 (with radiolabeled lauric acid) was: 80% expired as CO_2; 12% with the carcass; 4% unabsorbed from the gastrointestinal tract; 2.5% in the urine; and 1.2% in the liver (Nelson *et al.*, 1966).

The sorbitol-polyoxyethylene moiety is poorly absorbed and is mostly excreted in the feces. In a study with the radiolabel in the polyoxyethylene portion of polysorbate 20, 90% was excreted in the feces and 8% in the urine. No radioactivity was found in the liver, carcass or expired CO_2 (Nelson *et al.*, 1966).

Following intravenous administration of polysorbates to rats, the ester linkage of the polysorbates is hydrolyzed by blood lipases. Intravenous studies using polysorbate 20 (with radiolabeled lauric acid moiety) in rats showed that the fatty acid portion was metabolized and excreted mostly as expired CO_2. The sorbitol-polyoxyethylene moiety was not catabolized since no radioactivity was recovered as CO_2 when this portion of the molecule was labeled. Most of the radiolabeled polyoxyethylene moiety was excreted in the urine, although a small amount was found in the feces, indicating some biliary excretion; trace amounts were detected in the carcass and liver (Treon *et al.*, 1967).

Metabolism of polysorbates in humans appears to be similar to that in rats. Analysis of urine and feces from human volunteers who consumed 4.5 g of polysorbate 80 daily showed that 95% of the polyoxyethylene portion was excreted in the feces and 5% in urine; apparently, none was retained in the body (Culver *et al.*, 1951).

Acute Toxicity

The acute oral LD_{50} in rats range as high as >38,900 mg/kg (CIR, 1986) and the acute dermal LD_{50} is >3,000 mg/kg (CIR, 1986).

Irritation

Undiluted Polysorbate 20 produced essentially no irritation to the skin of rabbits or humans (CIR, 1986). When tested on human eyes, Polysorbate 20 up to concentrations of 40% produced no adverse effects (Marsh and Maurice, 1971). In rabbits, undiluted Polysorbate 20 produced minimal, transient eye irritation (CIR, 1986).

Sensitization

Polysorbate 20 was a moderate to strong skin sensitizer in the Magnusson-Kligman guinea pig maximization test (CIR, 1986). However, other Polysorbates (65 and 80) were not skin sensitizers when tested in the guinea pig skin sensitization assay (CIR, 1986).

The following is from the CIR report on polysorbates (CIR, 1986):

"Extensive clinical skin testing in the Schwartz prophetic patch test showed little potential for human skin irritation and no evidence of skin sensitization in a total of 580 subjects. A total of 1206 patients with eczema were tested in a chamber method 24-hour occlusive patch test for allergic contact dermatitis to a mixture of 5 percent Polysorbate 60 and 5 percent Polysorbate 80 in petrolatum; allergic reactions were shown by only 2 of the patients (< 0.2 percent). Several product formulations containing the Polysorbates have been tested for human skin sensitization on a total of 3481 subjects using a variety of testing methods; there were no reactions indicative of sensitization to any of the Polysorbates in these assays. Investigations with patients known to have skin disease revealed isolated instances of skin sensitization to Polysorbate 40 or 80. Intravenous injection of Polysorbate 80 produced hemodynamic changes in 5 patients. "

Repeated Dose Toxicity

Numerous long-term feeding studies have been conducted on polysorbates using a variety of animal species; only the key studies which have been the basis for the ADIs on polysorbates are summarized below.

When mixed feed including polysorbate 60 (2%, 5%, 10% or 25%) was administered to both male and female rats for two years, marked diarrhea was observed in the 10% and 25% groups, slight to moderate distention of the cecum in the 25% group, more slight

distention of the cecum in the 10% group and slightly suspicious changes in fat in the liver in the 25% group. The NOAEL is a dietary level of 5% (Fitzhugh *et al.*, 1959).

Rats were given in their feed 0, 5, 10 or 20% Polysorbate 60, 65 or 80 for two years and over four successive generations. At the 20% dose level, the most notable effect was diarrhea; there were also some effects on postnatal survival, lactation efficiency, breeding activity, growth rate, and longevity. The 10% dose level produced only diarrhea. The problems with diarrhea and reproduction at high dose levels were alleviated by the addition of fat to the diet. There were no adverse effects at the 5% level. No other adverse effects were noted. The NOAEL is a dietary level of 5% (Oser and Oser, 1957).

Groups of F344/N rats and $B6C3F_1$ mice of each sex were given diets containing 0, 3,100, 6,200, 12,500, 25,000 or 50,000 ppm polysorbate 80. All animals survived to the end of the studies. The final mean body weights of dosed rats and mice were similar to those of the controls. No clinical findings, changes in absolute or relative organ weights, or gross or microscopic lesions in rats or mice were related to polysorbate 80 administration. The NOAEL is 50,000 ppm (NTP, 1992a).

It is likely that the diarrhea noted in many feeding studies with the polysorbates resulted from having high concentrations of the unabsorbed polyoxyethylene sorbitan moiety within the intestinal lumen.

Genotoxicity

No specific studies were located for Polysorbate 20. One report mentioned a review in which stated that Polysorbate 20 was not mutagenic, but no information was provided (JFSC, 2007).

Based on Evaluation Report of Food Additives for Polysorbates (20, 60, 65 and 80), Polysorbate 60 was not mutagenic in the Ames test. Ames tests using two strains of *S. typhimurium* (TA98 and TA100) were performed in three independent assays and the results were negative both with and without metabolic activation (Kawachi *et al.*, 1981; Morita *et al.*, 1981; Inoue *et al.*, 1980). In addition, it did not induce *in vitro* transformation of hamster embryo cells (Inoue *et al.*, 1980).

A *B. subtilis* rec-assay was performed as a DNA repair study for Polysorbate 60, and while the assay was found to be positive for reverse mutation (JFSC, 2007), others obtained negative results (Kawachi *et al.*, 1981; Morita *et al.*, 1981). Several other studies, including clastogenicity studies, were conducted, but the results were negative (Kawachi *et al.*, 1981).

Polysorbate 80 was negative in rec-assays for DNA damage repair using *B. subtilis* and *E. coli* (Kawachi *et al.*, 1981). Polysorbate 80 was not mutagenic to *S. typhimurium* strains TA98, TA100, TA1535 and TA1537 with or without metabolic activation (Kawachi *et al.*, 1981; Morita *et al.*, 1981). In a chromosomal aberration study using

mammalian cells, the results were negative with or without metabolic activation (Kawachi *et al.*, 1981; Ichidate *et al.*, 1977). Polysorbate 80 was not genotoxic in two rodent micronucleus assays (Jenssen and Ramel, 1980; Scott and Topham, 1982); it was also negative in a dominant lethal study (Anderson *et al.*, 1977).

Carcinogenicity

There are no carcinogenicity studies on Polysorbate 20 that meets current standards.

Male and female Wistar rats were given in their feed 0, 5, 10 or 20% Polysorbate 60 for two years. There was no increased incidence of tumors in the Polysorbate 60-treated animals compared to the controls (Oser and Oser, 1957). In another two-year dietary study, there were no increased incidence of tumors in male and female Osborne-Mendel rats given 2, 5, 10 or 25% Polysorbate 60 (Fitzhugh *et al.*, 1959).

Male and female F344/N rats were given in their diet 0, 25,000, or 50,000 ppm Polysorbate 80 for up to 103 weeks. There were no significant changes in absolute or relative organ weights. The mean body weights in the treated male and female rats were similar to those of the controls throughout the studies. No clinical findings were associated with administration of Polysorbate 80. The survival of the treated males was lower than that of the controls. The incidence of adrenal medulla pheochromocytoma was marginally increased in high-dose males. The slight increase in incidence of pheochromocytoma in the high-dose males was judged to be of questionable significance based on historical control data. The incidence of adrenal medulla hyperplasia was increased in the 25,000 ppm males, but not in the 50,000 ppm males. The marginal increased incidence of pheochromocytoma in combination with increased incidence of hyperplasia were considered to be an equivocal finding (NTP, 1992a).

Male and female B6C3F_1 mice were given 0, 25,000, or 50,000 ppm Polysorbate 80 for up to 103 weeks. There were no significant changes in absolute or relative organ weights. Incidences of hyperplasia and inflammation of the forestomach were increased in females that received 50,000 ppm. The mean body weights in the treated males were similar to those of the controls throughout the studies. The final mean body weight of 50,000 ppm females was 11% lower than that of the controls. No clinical findings were associated with administration of Polysorbate 80. Survival were similar between the treated and control mice. No chemical-related increases in the incidences of neoplasms occurred in male or female mice. The incidences of squamous hyperplasia and inflammation of the forestomach were significantly increased in high-dose male and female mice; forestomach ulcers were significantly increased in high-dose females (NTP, 1992a).

Reproductive/Developmental Toxicity

Pregnant Sprague-Dawley rats were given by oral gavage 0, 500 or 5,000 mg/kg Polysorbate 20 during gestation days (GD) 6-15. There was no maternal toxicity, and

there was no significant differences in body weight between treated and control animals. Maternal weight gain during GD 6-15 was decreased by 14% in the high-dose group relative to control animals. There was no treatment-related effects on organs weights, number of corpora lutea per dam, the number of implantation sites per dam or the percent preimplantation loss per litter. There was also no adverse effects on the growth, viability or morphological development of the conceptuses. The maternal and developmental NOAELS for this study were considered to be 500 and 5,000 mg/kg/day, respectively (NTP, 1992b).

Key Study/Critical Effect for Screening Criteria

In 1973, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) evaluated the effects of Polysorbates 20, 40, 60, 65, and 80 when used as food additives. JEFCA established an ADI of 0-25 mg/kg/day for the group of Polysorbates (JECFA, 1973). The study on which the ADI was based was the two-year feeding study by Fitzhugh *et al.*, 1959, in which the NOAEL was determined to be 5% (equivalent to 2,500 mg/kg/day).

In 1978, the EU's Scientific Committee on Food (SCF) evaluated the safety of polysorbates, mainly based on the two-year feeding study on Polysorbate 60 (SCF, 1978). SCF assigned an interim ADI of 0-25 mg/kg/day for the polysorbate group, but requested data from a 90-day oral toxicity study and a metabolism study in one animal species, which SCF considered necessary for a final evaluation.

In 1983, the SCF conducted a re-evaluation based on a 13-week oral study in which rats were fed 0, 1, 2 or 5% Polysorbate 60 (equivalent to 500, 1,000 or 2,500 mg/kg/day, respectively) (BIBRA, 1981). SCF accepted a review of the existing metabolism data in lieu of the requested data in 1978 (SCF, 1978). A permanent group ADI for the polysorbates was established at 0-10 mg/kg/day, after application of a 100-fold uncertainty factor to the lowest NOAEL of 2% in the diet from the 13-week feeding study. In 1992, SCF further evaluated the ADI for the polysorbates, in light of the recently conducted NTP bioassay on Polysorbate 80 (NTP, 1992), and concluded that the ADI need not be changed (SCF, 1993).

The U.S. FDA has established a group ADI for the polysorbates at 1,500 mg/person/day (0-25 mg/kg/day). (FDA, 1999).

The ADI of 25 mg/kg/day established by JECFA and the U.S. FDA will be the basis of the oral RfD and drinking water guideline for sorbitan, monododecanoate poly(oxy-1,2-diethanediyl) [Polysorbate 20] since the findings of the 13-week rat feeding study (BIBRA, 1981), which was the basis for the ADI established by SCF, is unavailable for review.

Oral RfD = 2,500/100 = 25 mg/kg/day

Drinking water guideline value = 87.5 ppm

Toxicity Profile

Sulfuric acid
(CAS No. 7664-93-9)

Sulfuric acid (H_2SO_4) will dissociate completely in aqueous media at physiological pH to H^+ and SO_4^{2-}. The pK_a of sulfuric acid is 1.92.

Acute Toxicity

The oral LD_{50} in rats was reported to be 2,140 mg/kg (Smyth *et al.*, 1969). The acute LC_{50} values are: 0.375 to 0.425 mg/L for rats; 0.6 to 0.85 mg/L for mice; and 1.47 to 1.61 mg/L for rabbits (OECD, 2001).

Irritation

Undiluted sulfuric acid is corrosive to the skin and eyes (OECD, 2001). A 10% solution of sulfuric acid in water has been shown to be non-irritating to the skin of rabbits, guinea pigs and humans (Nixon *et al.*, 1975; 1990). Instillation of 0.1 ml of a 10% solution of sulfuric acid was shown to be non-irritating to the eyes of rabbits when added to the conjunctival sac (Jacobs and Martens, 1989; Jacobs, 1992). Other studies which added a 10% solution of sulfuric acid directly to the eyes of rabbits showed severe irritation (Griffith *et al.*, 1980; Murphy *et al.*, 1982).

Sensitization

No animal sensitization studies have been conducted on sulfuric acid. There have been no reported cases of dermal sensitization in humans (OECD, 2001).

Repeated Dose Toxicity

There have been a number of repeat dose toxicity studies conducted by the inhalation route on sulfuric acid, but no studies were located by the oral or dermal routes.

Genotoxicity

Sulfuric acid was not mutagenic in the Ames test using various strains of *S. typhimurium* and in *E. coli* with and without metabolic activation (OECD, 2001). No *in vivo* genotoxicity studies have been conducted on sulfuric acid.

Carcinogenicity

Animal carcinogenicity studies have been conducted with sulfuric acid solutions or mists. These studies cannot be used for risk assessment purposes due to significant methodological deficiencies.

Reproductive/Developmental Toxicity

No studies were found.

Key Study/Critical Effect for Screening Criteria

No toxicity studies on sulfuric acid were identified. The Australian drinking water guideline values are available for pH (H^+) and sulfate which could applicable to sulfuric acid.

Toxicity Profile

Talc
(CAS No. 61789-40-0)

Talc refers to both mineral talc and industrial mineral products that are marketed under the name talc and contain proportions of mineral talc that range from about 35% to almost 100%. Industrial talc generally refers to products that contain abundant minerals other than talc; cosmetic talc now normally contains >98% talc but the content may have been lower in the past. Pharmaceutical talc contains >99% talc. Talcum powder is cosmetic-grade talc.

Talc is a mineral composed of hydrated magnesium silicate with the chemical formula $Mg_3Si4O_{10}(OH)_2$ or $H_2Mg_3(SiO_3)_4$. Talc is not soluble in water.

The U.S. Food and Drug Administration (FDA) regulates talc and states that it is generally recognized as safe for use in color additives in foods, drugs and cosmetics, and in paper, paper products, cotton and cotton fabrics that come into contact with food. The Food Chemical Codex (2003) provides specifications for food-grade talc, including the statement that "talc derived from deposits that are known to contain associated asbestos is not food grade." Under the voluntary guidelines initiated in 1976, the Cosmetic, Toiletry, and Fragrances Association stated that all cosmetic talc should contain at least 90% platy talc (hydrated magnesium silicate) that is free from detectable amounts (<0.5%) of fibrous, asbestos minerals.

Toxicokinetics (Oral)

The absorption and disposition of ^{3}H-labeled talc in rats, mice, and guinea pigs administered a single oral dose was studied by Phillips *et al.* (1978). The oral doses were 50 mg/kg for rats, 40 mg/kg for mice, and 25 mg/kg for guinea pigs. In rats, mice, and guinea pigs, more than 95% of the dose was excreted in the feces 3 to 4 days after dosing. Less than 2% of the radioactivity was recovered in the urine. This radioactivity probably reflected contamination of urine samples with feces. No radioactivity was found in the liver or kidneys of these animals. This information suggests that talc is not absorbed from the gastrointestinal tract following oral exposure.

Acute Toxicity

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Male and female Wistar rats were given in their diet 0 or 50 mg/kg of commercial talc [characteristics unspecified] for the life of the animals (average survival was 702 and 649 days, respectively). There was no significant difference in the talc-fed animals compared with control animals (Gibel *et al.*, 1976).

Male and female Wistar-derived rats were given in their diet 100 mg Italian talc (grade 00000; ready milled; mean particle size, 25 μm; containing 92% talc, 3% chlorite, 1% carbonate minerals and 0.5–1% quartz) per rat per day for 5 months (talc-containing diet was actually given for 101 days) and were then maintained on basal diet for life (average survival, 614 days). No differences in tumor incidence were noted between treated animals and control animals (eight/sex for an average survival of 641 days) (Wagner *et al.*, 1977).

In humans and experimental animals, the effects of talc are dependent on the route of exposure, and the dose and properties of the talc. Talc pneumoconiosis was somewhat more prevalent and severe among miners exposed to talc containing asbestiform minerals and/or asbestos than among those exposed to talc without such contaminants. However, the role of quartz and asbestos in the observed pneumoconiosis could not be ruled out. Among drug users, intravenous injection of talc present as a filler in the drugs resulted in microembolization in a variety of organs and alterations in pulmonary function. In animal studies, talc has been shown to cause granulomas and mild inflammation when inhaled. Observations of the effects that occurred in the lungs of rats exposed by inhalation to talc suggested that the operative mechanisms may be similar to those identified for carbon black, and talc is known to cause the release of cytokines, chemokines and growth factors from pleural mesothelial cells.

IARC: There is *inadequate evidence* in humans for the carcinogenicity of inhaled talc not containing asbestos or asbestiform fibres. There is *limited evidence* in experimental animals for the carcinogenicity of talc not containing asbestos or asbestiform fibres. Inhaled talc not containing asbestos or asbestiform fibres is *not classifiable as to its carcinogenicity (Group 3).*

Genotoxicity

The IARC (1987) review of talc included unpublished results from a 1974 study conducted by Litton Bionetics that showed no mutagenic activity for talc *in vitro* or *in vivo.* Talc did not induce mutations in *Salmonella typhimurium* strains TA1530 or HisG46, or in the yeast, *Saccharomyces cerevisiae.* No chromosomal aberrations were observed in human fibroblasts treated with talc *in vitro. In vivo* tests conducted in rats gave negative results for induction of chromosomal aberrations in bone marrow cells and dominant lethal mutations in germinal cells.

Three samples of respirable talc failed to elicit significant unscheduled DNA synthesis (10, 20 and 50 μg/cm^2, 24 hours), sister chromatid exchange or aneuploidy (2, 5, 10 and 15 μg/cm^2, 48 hours) in rat pleural mesothelial cells, in contrast to various positive controls. The three samples, *i.e.* Spanish talc (No. 5725), Italian talc (No. 5726) and French talc (No. 7841), contained 90–95% talc; the remaining contents were chlorite and dolomite. Electron microscopy analysis revealed that talc particles were taken up by the rat pleural mesothelial cells, but no aneuploidy was observed in metaphases (Endo-Capron *et al.*, 1993).

Reproductive Toxicity

No data are available.

Developmental Toxicity

No teratologic effects were observed in hamsters, rats, mice, or rabbits after oral administration of talc. The doses used were 1,600 mg/kg for rats and mice on days *6* through 15 of gestation; 1,200 mg/kg for hamsters on day 6 through 10 of gestation; and 900 mg/kg for rabbits on days 6 through 18 of gestation.

Key Study/Critical Effect for Screening Criteria

There are no adequate studies for which to derive a oral reference dose. Talc is poorly absorbed from the gastrointestinal tract, if at all, and the limited data available by the oral route indicate that talc is essentially non-toxic by the oral route of exposure.

Toxicity Profile

Tributyl Tetradecyl Phosphonium Chloride [TTPC]
(CAS No. 81741-28-8)

Limited toxicity information was located for this alkyl phosphonium salt.

Acute Toxicity

An oral LD_{50} in rats was reported to be 1,002 mg/kg. The 4-hour LC_{50} to rats is <0.9 mg/L (aerosol).

Irritation

TTPC is corrosive to the skin and eyes.

Sensitization

TTPC is not a skin sensitizer.

Repeated Dose Toxicity

No data were found.

Genotoxicity

TTPC tested negative in an Ames test.

Carcinogenicity

No data were found.

Reproductive Toxicity

No data were found.

Developmental Toxicity

No data were found.

Key Study/Critical Effect for Screening Criteria

No data are available for determining the critical effect and the LOAEL/NOAEL for an oral reference dose.

Reference

Material Safety Data Sheet for Bellacide 350, BWA Water Additives, SDS No. 10794, Report Date: 10/03/2009.

Santos

APPENDIX F.4 SCHLUMBERGER CLEARFRAC XT

Toxicity Profile

Acetic acid
(CAS No. 64-19-7)

Acetic acid dissociates in aqueous media to H^+ and the acetate anion ($CH_3CO_2^-$). It is naturally occurring as the acid in apple cider vinegar and other fruit-derived products. It and several of its salts are commonly used as food additives (*e.g.*, as flavor enhancers) and are listed as Generally Recognized as Safe (GRAS) by the U.S. Food and Drug Administration (FDA).

pH: 2.5 at 50 g/L and 20°C
pK_a: 4.76 @ 20°C

Acute Toxicity

The oral LD_{50} in rats is 4,950 mg/kg, and the dermal LD_{50} in rabbits is 1,060 mg/kg. The 4-hour LC_{50} in rats is 11.4 mg/L.

Irritation

In the EU, acetic acid is classified as a skin and eye irritant at concentrations <25%. At ≥25%, it is classified as corrosive to the skin.

Sensitization

No data are available.

Repeated Dose Toxicity

In an 8-month study, rats dosed with 60 mg/kg acetic acid (three times per week) developed hyperplasia in the esophagus and forestomach.

Genotoxicity

Acetic acid was not mutagenic to *Salmonella typhimurium* strains TA 98, TA 100, TA 1535, TA 1537, and TA 1538 in an *in vitro* bacterial mutation assay with or without metabolic activation. Acetic acid (in media adjusted to a pH of 8.5) was also not genotoxic in an *in vitro* chromosomal aberration test using Chinese Hamster Ovary cells with or without metabolic activation.

Carcinogenicity

No adequate carcinogenicity studies have been conducted on acetic acid.

Reproductive Toxicity

No studies could be located.

Developmental Toxicity

There were no effects on implantations or on maternal or fetal survival in mice, rats, or rabbits at doses up to 1,600 mg/kg.

Key Study/Critical Effect for Screening Criteria

There are no repeat dose toxicity studies that were considered adequate for human health risk assessment. The only study reported on the toxicity of acetic acid by oral gavage showed effects of irritation (probably due to the pH of acetic acid) at the site of contact in the gastrointestinal tract. No systemic effects were reported.

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) has maintained a group ADI of "not limited" for acetic acid and its potassium and sodium salts.

The Australian drinking water guidance value for pH may apply to acetic acid.

Toxicity Profile

Reaction mass of 5-chloro-2-methyl-4-isothiazolin-3-one and 2-methyl-2H-isothiazolin-3-one [3:1]
(CAS No. 55965-84-9)

Acute Toxicity

The oral LD_{50} of Kathon WT (1.5% a.i.) is >5,000 mg/kg (>75 mg a.i./kg) in male rats and >3,310 mg/kg (~49.6 mg a.i./kg) in female rats. The oral LD_{50} of Acticide 14 (14% a.i.) is 472-490 mg/kg (~66 to 69 mg a.i./kg) in rats (combined sexes); and 465 mg/kg (69 mg a.i./kg) in male rats and 393 mg/kg (59 mg a.i./kg) in female rats.

The dermal LD_{50} of Kathon CG is >5,000 mg/kg (>75 mg a.i./kg) in female rabbits. The dermal LD_{50} of Acticide 14 (14% a.i.) is 1,008 mg/kg (141 mg a.i./kg) in rats (combined sexes).

The inhalation LC_{50} of Kathon 886F (13.9% a.i.) in male and female rats is 2.36 mg/L (0.33 mg a.i./L).

Irritation

Undiluted Kathon MW (1.5% a.i.) and Acticide 14 (14% a.i.) were corrosive to rabbit skin. Undiluted Kathon CG was severely irritating to the eyes of rabbits. Kathon RH 886T at 100 ppm (0.01% a.i.) was non-irritating to the eyes of rabbits.

Sensitization

CMI/MI has been tested in the guinea pig Buehler and Magnusson-Kligman tests and has been shown to be a strong skin sensitizer. It is also a strong contact allergen in humans.

Repeat Dose Toxicity

Rats were exposed to CMI/MI in a powdered commercial diet. CMI/MI concentrations were increased over the 13-week period (initial concentration up to week 2, intermediate concentration week 3-4, final concentration week 5 to 13). Concentrations in the control and CMI/MI groups were: 0/0/0, 40/57/80, 132/187/260, 400/570/800 ppm. There were no mortalities and no effects on body weight or food consumption. In each group, some animals showed slight alopecia or reddened raw or scabbed areas on the skin. There were no other differences in general behavior or appearance. There were no treatment-related changes in hematological, biochemical, urinary parameters nor any pathology. No systemic toxicity was observed up to and including the highest dose of either CMI/MI

(800 ppm, equivalent 29.1 mg a.i./kg/day). The NOAEL in this study is 800 ppm (29.1 mg a.i. /kg/day).

Rats were exposed to CMI/MI via their drinking water at concentrations of 25, 75 or 225 ppm a.i. for three months (equivalent to an average intake of 2.38, 6.28 and 16.3 mg/kg/day in males and 4.06, 10.8, and 24.7 mg/kg/day in females). Two additional groups of rats were given tap water or tap water containing the inorganic ions present in the CMI/MI solution, at a concentration equal to that in the high dose group (225 ppm). This solution is referred to as the ion control solution. There were no mortalities in either sex at any dose level. There were no treatment-related effects on body weight up to the mid dose. A significant decrease in body weight was seen in males at the high dose during the first two weeks of the study. Food consumption was significantly decreased in males at all dose levels and in females mid and high dose groups during the first few weeks of dosing. Water consumption was significantly decreased at all concentrations. No overt clinical signs or ophthalmic were seen in any group throughout the 13 week toxicity or the reproductive phase. No adverse effects were seen in the examinations. No hematological treatment-related changes were seen in either sex at any dose level. There was a significant decrease in globulin and an increase in the albumin/globulin (A/G) ratio in males in both the high concentration and in the ion control groups, after 13 weeks of treatment. A significant decrease in total protein was also seen high concentration group, but was not seen in the ion control group. Females in the high concentration group showed a modest (40%) increase in SGOT (AST, aspartate aminotransferase) levels after 13 weeks of dosing. No changes were observed at any dose in mixed-function oxidase activities of the liver. At the end of 13 weeks of treatment, there was a significant increase in relative liver weight in males and in relative kidney weight in females at the high concentration but without any correlative changes in organ pathology. Histology revealed a local irritation of the glandular mucosa of the stomach in 7 of 15 males and 5 of 15 females at the high concentration. These subtle low level changes did not occur at the low or mid concentration nor were they present in either control group. No other compound related changes were seen. Reproductive organs at all doses were comparable to the control. The NOEL in this study was considered to be 75 ppm a.i. (equivalent to 6.28 and 10.8 mg/kg body weight/day in males and females, respectively), based primarily on irritation of the glandular stomach at the high dose. The No Observed Adverse Effect Level (NOAEL) is 225 ppm a.i. (equivalent to 16.3 and 24.7 mg/kg body weight/day in males and females, respectively), the highest dose tested, since no adverse effects were observed on the histopathology of any tissues or organs distant from the site of dosing.

Genotoxicity

The results of the *in vitro* mutagenicity tests were equivocal. In bacterial reverse mutation tests, CMI/MI was positive in *Salmonella* strain TA100 but was predominantly negative in other strains commonly tested strains. CMI/MI was mutagenic in the mouse lymphoma assay with and without metabolic activation. Effects at the Tk locus was seen both with and without S-9, but were enhanced with S9 mix. CMI/MI was not genotoxic

in the *in vitro* unscheduled DNA synthesis (UDS) assay with primary rat hepatocytes or in an *in vitro* chromosomal aberration test with Chinese hamster lung cells.

The *in vivo* studies indicated that CMI/MI does not have relevant mutagenic potential *in vivo*. The positive mutagenic effect of CMI/MI found in *in vitro* gene mutation assays was not confirmed in the sex-linked recessive lethal test in *Drosophila melanogaster* nor in two unscheduled DNA synthesis (UDS) studies in the rat. CMI/MI also did not show any increase in cells with micronuclei in mice nor did it induce chromosomal aberrations in rat bone marrow cells.

Carcinogenicity

In a two-year rat chronic study, Kathon 886 is given as 14.2% active ingredient with a pH between 2-3. In the document with compiled batch information for Kathon the active ingredient is 13.2, [10.13 % CMI/ 3.85% MI] with 15.4% magnesium nitrate and 9.0% magnesium chloride. The dose levels were 0, 30, 100 and 300 ppm (equivalent to: 0, 2.0, 6.6, 17.2 mg a.i./kg/day in males and 0, 3.1, 9.8, 25.7 mg a.i./kg/day in females. There were no deaths. There were no treatment-related effects on body weight or body weight gain at doses or food consumption up to and including the mid dose group. A treatment-related and concentration-dependent decrease in water consumption was seen in both sexes in all treated groups throughout the study. These decreases ranged from 0-22% at low dose 3-30% at mid dose and 15-40% at high dose. These decreases appear to be due to the unpalatability of the CMI/MI and not its inorganic stabilizer salts since the water consumption in the salt control was comparable to the tap water control throughout the study. Based on the average daily water consumption, the high dose was judged to be a maximum tolerated dose. The decreases in body weight and body weight gain were seen in high dose animals throughout the study and may be secondary to decreased water consumption. No treatment-related clinical effects were recorded. No treatment-related ophthalmic, hematological. biochemical or urinary changes were noted. Organ weights were comparable to the control. No effects on type or incidence of neoplasms were seen at up to and including the high dose (males: 17.2 a.i.; females 25.7 mg a.i./kg/day). Slight to moderate forestomach hyperplasia was seen at both mid and high dose groups. Gastric irritation was the primary effect observed. No adverse effects on the histopathology of any other tissues/organs were observed away from the site of dosing. No systemic effects were observed. The NOEL in this study was considered to be 30 ppm a.i. (2.0 to 3.1 mg a.i./kg/day), based primarily on gastric irritation of the stomach at 100 and 300 ppm a.i.. The NOAEL was considered to be 300 ppm a.i. (17.2 to 25.7 mg/a.i./kg/day), since no evidence of systemic toxicity was observed at any dose and there was no adverse effects on the histopathology of any tissues/organs distant from the site of dosing at any dose.

Reproductive/Developmental Toxicity

A one-generation reproductive toxicity study was combined with the 13-week drinking

water study reported above in the repeated dose toxicity section. Reproductive capability was similar in all groups. Litter size and survival at birth was also similar in all groups. One dam at the high concentration lost the entire litter by day 4 due to a lactation problem. This is not uncommon and was not considered treatment related. Pups of the other high concentration group dams, except one, survived and thrived to day 21. Thus, no adverse effects were observed on reproductive capability of male and female rats and no effects were observed on fetal health or pup survival (to day 21) up to and including the high dose (equivalent to 16.3 and 24.7 mg/kg/day in males and females, respectively].

In a two-generation reproductive toxicity study, rats were dosed with CMI/MI (Kathon 886F: 11.1% CMI, 3.7% MI a.i.) at concentrations of 0 (control), 0 (magnesium salt control), 30, 100 or 300 ppm a.i. For the P1 generation, this was equivalent to 0, 2.8-4.4; 8.5-11.8, and 22.7-28.0 mg a.i./kg/day; and in the P2 generation 0, 4.3-5.5, 13.4-16.0, and 35.7-39.1 mg a.i./kg/day. There were no treatment related effects on survival, food consumption or overt signs of toxicity. A decrease in bodyweight gain was noted initially in the P1 generation. This was thought to be linked to reduced water consumption since significant dose-related reduction in water consumption was seen at all concentrations in both the P1 and P2 generations, during the premating, gestation and lactation stages. Treatment-related histopathological changes were seen in the stomach in the P1 and P2 generation. These included erosions of the glandular mucosa, edema and inflammation in the submucosa of the glandular and nonglandular stomach, with hyperplasia and hyperkeratosis of the nonglandular stomach at the 100 and 300 ppm a.i. Other histopathological changes were seen but were not dose dependent.The estrus cycle in P1 or P2 females at any treatment level was comparable with the controls, as was the sperm motility, morphology, testicular sperm count or caudal epididymal reserves of P1 or P2 males. All other endpoints (gestation index, gestation length, number of pups per litter or treatment-related gross findings in F1 or F2 pups) were similar to those in the controls in either generation. The study authors considered that rats exposed to CMI/MI in the drinking water through two generations had a NOAEL of 30 ppm a.i. (2.8-4.4 mg/kg/day in the P1 animals; 4.3-5.5 mg/kg/day in the P2 animals) for parental animal toxicity, based on the gastric irritation of stomach at higher doses. The NOEL for reproductive toxicity is 300 ppm a.i. (22.7-28.0 mg/kg/day in the P1 animals; 35.7-39.1 mg/kg/day in the P2 animals), the highest dose tested. There were no effects on fertility or fetal development at any dose level.

In a rat oral gavage developmental toxicity study on Kathon 886 (13.9% a.i.), the developmental NOEL for CMI/MI is >15 mg a.i./kg during organogenesis (highest dose tested). In a rat oral gavage developmental toxicity study on Acticide 14 (10.2% CMi/ 4% MI), the NOAEL for maternal toxicity is <3.95 mg a.i./kg; the NOAEL for teratogenicity is >19.6 mg a.i./kg; and the NOAEL for embryotoxicity is >19.6 mg a.i./kg. In a rabbit oral gavage developmental toxicity study on Acticide 14 (10.2% CMI/ 4% MI), the developmental NOAEL is >5.49 mg a.i./kg; the NOAELs for maternal toxicity and fetal toxicity are 1.41 mg a.i./kg. In a rabbit oral gavage developmental toxicity study on Kathon MW (13.9% a.i.), the NOEL for maternal toxicity is 2 mg a.i./kg; the developmental NOEL is 8 mg a.i./kg, the highest dose based on severe

maternal toxicity at 20 mg a.i./kg.

Key Study/Critical Effect for Screening Criteria

A two-year dietary study was conducted in rats with CMI/MI (13.2% active ingredient). No systemic effects were observed. There was, however, gastric irritation of the stomach at 100 and 300 ppm. The NOEL for this study is 30 ppm (equivalent to 2.0 and 3.1 mg a.i./kg/day for males and females, respectively). The NOEL of 2.0 mg/kg/day will be used for deriving a drinking water guidance value.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral Reference Dose = 2/100 = 0.02 mg/kg/day

Drinking water guidance value = 0.07 ppm

Reference

Toxicity Profile

Choline chloride
Cholinium chloride
(CAS No. 67-48-1)

Choline chloride, also known as cholinium chloride, is a quaternary amine salt. It dissociates in water into the corresponding positively charged quaternary hydroxyl alkylammonium ion and the negatively charged chloride ion.

Choline chloride has been reviewed in the OECD-SIDS program (OECD, 2004).

Acute Toxicity

The oral LD_{50} in rats was reported to be between 3,150 and 5,000 mg/kg (BASF AG, 1963a, 1969).

Irritation

Application of a 70% aqueous solution to the skin of rabbits for 20 hours under occlusive conditions resulted in only minor skin irritation (BASF AG, 1963b). Slight eye irritation was seen in the eyes of rabbits after instillation of a 70% aqueous solution of choline chloride; no effects were seen one day after exposure (BASF AG, 1963c).

Sensitization

No data are available in animals. In a Human Repeated Insult Patch Test, there was no evidence of dermal sensitization in two hundred subjects given 0.5% (w/v) aqueous solution of choline chloride during the induction phase and 0.2% (w/v) aqueous solution during the challenge phase (Colgate-Palmolive, 2003).

Repeated Dose Toxicity

A 72-week feeding study was conducted to investigate the impact of choline chloride on the liver tumor promoting activity of phenobarbital and DDT in diethylnitroamine-initiated Fischer 344 rats (Shivapurkar *et al.*, 1986). Animals received approximately 500 mg/kg-day choline chloride. Following the end of the exposure period, the animals were keep on the same untreated diet as the control group until study termination at week 103. Histopathology was limited to the liver and organs that developed gross abnormalities. There were no significant differences between treated and control animals on survival rates, body weights, and relative liver weights. Neither was there any

increased number of neoplastic liver nodules, hepatocellular carcinomas, lung tumors, leukemia nor other tumors between treated and control animals. The NOAEL for choline chloride in this study is 500 mg/kg/day.

In humans, oral administration of 10,000 mg/day choline chloride in a pilot study treating a small number of patients with Alzheimer's disease, resulted in a slight hypotensive effect (Boyd *et al.*, 1977). This dose was regarded as a LOAEL by the Standing Committee on the Scientific Evaluation of Dietary Reference Intake (2000).

Genotoxicity

Choline chloride was not mutagenic to bacteria in reverse mutation assays (Haworth *et al.*, 1984; JETOC, 1997; Litton Bionetics, 1977).

A small, but statistically significant, and dose-related increase in sister chromatid exchanges (SCEs) in Chinese Hamster Ovary (CHO) cells was reported at 50 and 500 μg/ml choline chloride in the absence of S9 only (Bloom *et al.*, 1982). No higher concentrations were examined. These results could not be confirmed in another study using CHO cells at concentrations of choline chloride up to 5,000 μg/ml. (Galloway *et al.*, 1985).

In a gene conversion assay with *Saccharomyces cerevisiae* strain D4, choline chloride was negative in the presence and absence of metabolic activation (Litton Bionetics, 1977).

No *in vivo* genotoxicity studies were available.

Carcinogenicity

No studies were located.

Reproductive Toxicity

No reliable studies have been conducted that address female fertility or reproductive toxicity by a relevant route of exposure.

Developmental Toxicity

Pregnant female mice were given in their feed 1,250 to 20,000 mg/kg choline chloride during gestational days 1 to 18 (BASF AG, 1966). Maternal body weight gain was reduced in all treated groups except for the 1,250 mg/kg group. Determination of maternal weight gain of dams with embryonic/fetal absorptions showed that there was no

almost net weight gain at ≥4,160 mg/kg and net weight loss in the 20,000 mg/kg group. All fetuses were resorbed in the 20,000 mg/kg group. Embryonic/fetal lethality of 35% and 69% were seen in the 4,160 and 10,800 mg/kg groups, respectively. No resorptions occurred in the 1,250 mg/kg group. Developmental toxicity was seen in all but the 1,250 mg/kg group. No statistically significant increases in malformations were observed in any dose group. The NOAELs for maternal and developmental toxicity is 1,250 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The Standing Committee on the Scientific Evaluation of Dietary Reference Intakes selected hypotension as the critical effect from the study by Boyd *et al.* (1977) when deriving a Tolerable Upper Intake Level. Boyd *et al.* (1977) reported a LOAEL of 10,000 mg/day choline chloride (7,500 mg/day choline). An uncertainty factor of 2 was chosen because of the limited data regarding hypotension and the inter-individual variation in response to cholinergic effects. Thus, the value for the Tolerable Upper Intake Value for repeated exposure of adults to choline is 3,500 mg/day choline.

The oral RfD for choline chloride is derived by using the LOAEL of 10,000 mg/day from the Boyd *et al.* (1977) study, which is divided by an uncertainty factor of 2, to obtain a value of 5,000 mg/day or 71 mg/kg/day for a 70 kg person.

Oral RfD = 71 mg/kg/day

Drinking water guideline value = 248 ppm

Toxicity Profile

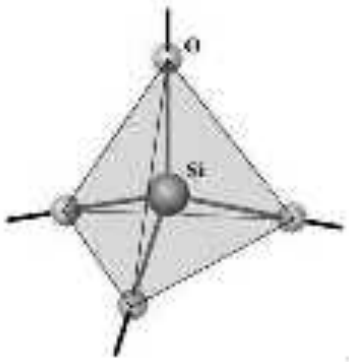
Crystalline Silica, Cristobalite
(CAS No 14464-46-1)

Crystalline Silica, Quartz
(CAS No. 14808-60-7)

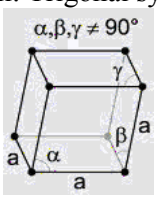
Silica is an off-white granule that occurs naturally in various crystalline and amorphous or other non-crystalline forms. Crystalline silica is characterized by silicon dioxide (SiO_2) molecules oriented in fixed, periodic patterns to form stable crystals. The primary crystalline form of silica is quartz. Other crystalline forms of silica include cristobalite, tripoli and tridymite. Particle size is a key determinate of silica toxicity, since toxicity is restricted to particles that are small enough to be deposited into the target regions of the respiratory tract.

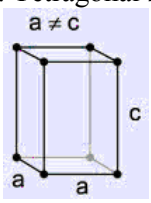
Oral Exposure

No oral studies were located; however, crystalline silica is not expected to exhibit toxicity by the oral route. Although absorption studies were not found for crystalline silica, kinetic studies on amorphous silica show no absorption from the gastrointestinal tract.



Dermal Exposure





No dermal studies were located; however, crystalline silica is not expected to exhibit toxicity by the dermal route.

Inhalation Exposure

See attached OECD-SIDS Initial Targeted Assessment Profile on Quartz and Cristobalite, SIAM 32, 19-21 April 2011.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

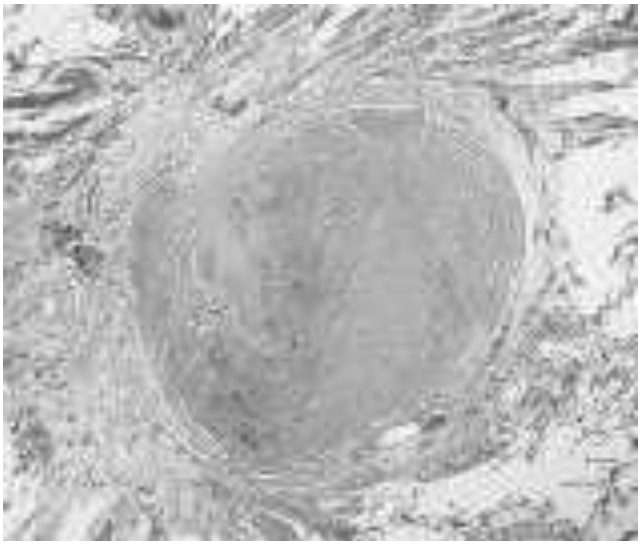


Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3
Sister chromatid exchange	0/1		0/1[c]	1/1	0/2	1/1
Micronucleus	2/3	0/1	2/2[b]	1/1	4/5	1/2
Chromosome aberration	0/1			1/1	0/1	1/1
Aneuploidy/polyploidy	0/3				0/3	
Cell transformation	4/4				4/4	
Hprt mutation	1/2	2/2[a]	1/1[b]		2/3	2/2
Oxidative DNA damage		4/5	2/2		2/2	4/5
DNA binding		1/1				1/1
p53 activation		0/1				0/1

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

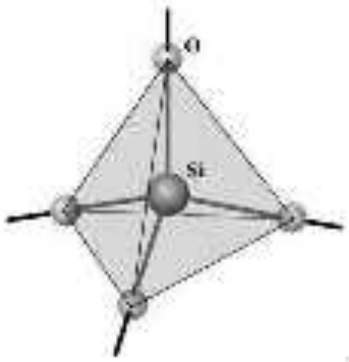
bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

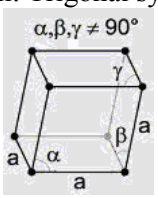
Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

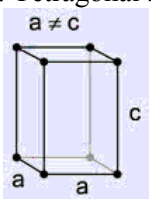
Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.



OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.





RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

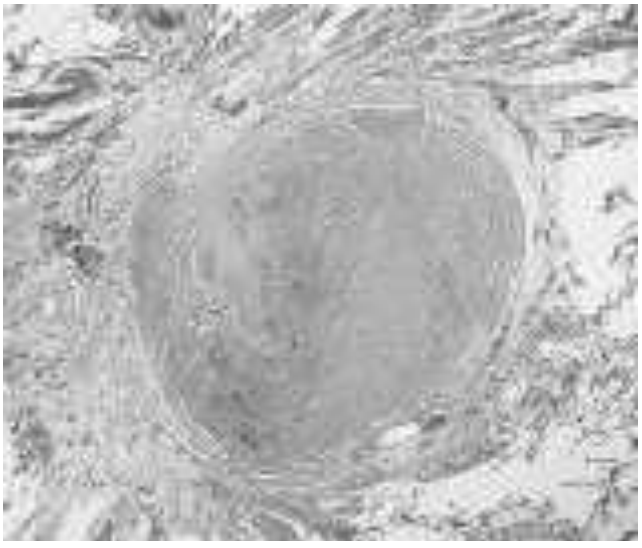

Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3
Sister chromatid exchange	0/1		0/1[c]	1/1	0/2	1/1
Micronucleus	2/3	0/1	2/2[b]	1/1	4/5	1/2

Cell transformation	4/4				4/4	
Hprt mutation	1/2	2/2[a]	1/1[b]		2/3	2/2
Oxidative DNA damage		4/5	2/2		2/2	4/5
DNA binding		1/1				1/1
p53 activation		0/1				0/1

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.

OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.

RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

Toxicity Profile

Erucic amidopropyl dimethyl betaine
(CAS No. 149879-98-1)

Erucic acid is the fatty acid of erucic amidopropyl dimethylbetaine. It is a mono-unsaturated omega-9 fatty acid (22:1 ω9). No toxicity data could be located on erucic amidopropyl dimethyl betaines. Thus, this toxicity profile is based on the data on cocoamidopropyl betaines.

Cocamidopropyl betaines are mainly a mixture of C_{12}-C_{18} fatty acids from hydrolysis of coconut oil. Coconut oil has a mixed fatty acid composition, which varies slightly, as it is a natural product. Lauric acid - resulting in lauramidopropyl betaine - is the major ingredient of coconut oil.

Acute Toxicity

The acute toxicity of cocoamidopropyl betaine (30-35.5% aqueous solution) in rats is low. The oral LD_{50} is $\geq$4,900 mg/kg, and the dermal LD_{50} is >2,000 mg/kg.

Irritation

A 30% aqueous solution of cocoamidopropyl betaine was only very slightly irritating to the skin of rabbits. In human studies, up to 3% solutions were weakly irritating. A 5-10% solution of cocamidopropyl betaine produced mild to moderate irritation to the eyes of rabbits; solutions containing 15% were irritating to highly irritating; and a 30% aqueous solution was irritating with irreversible damage.

Sensitization

The sensitizing potential of cocoamidopropyl betaine in humans is low. Commercial cocoamidopropyl betaine may, however, contain impurities identified as sensitizers (amidoamine and/or 3-dimethylaminopropylamine) which may explain positive results in human patch tests. There is no evidence for a photosensitizing potential.

Repeated Dose Toxicity

Rats were given a 30% aqueous solution of cocoamidopropyl betaine by oral gavage at doses of 0, 250, 500 or 1,000 mg/kg/day (corresponding to about 0, 75, 150, and 300 mg active substance/kg/day, respectively) 5 days/week for 28 days (Henkel KgA, 1991). The only treatment-related findings were forestomach lesions at the highest dose level,

probably as a result of the irritant effect of the test substance. The NOAEL for this study is 500 mg/kg/day (150 mg cocoamidopropyl betaine/kg/day).

Rats were given a 30% aqueous solution of cocoamidopropyl betaine by oral gavage at doses of 0, 250, 500 or 1,000 mg/kg/day (corresponding to about 0, 75, 150, and 300 mg active substance/kg/day, respectively) five days/week for 90 days (Th. Goldschmidt AG, 1991). The only treatment-related findings were forestomach lesions at the 500 and 1,000 mg/kg dose levels , probably as a result of the irritant effect of the test substance. The NOAEL for this study is 250 mg/kg day (75 mg cocoamidopropyl betaine/kg/day).

Genotoxicity

There is no evidence for a genotoxic potential of cocoamidopropyl betaine. A 30% aqueous solution of cocoamidopropyl betaine was not genotoxic i*n vitro* in either a bacteria mutation test or in a mouse lymphoma test. A limited intraperitoneal mouse micronucleus test with 27 % active cocamidopropyl betaine was negative.

Carcinogenicity

No valid carcinogenicity studies have been conducted.

Reproductive Toxicity

No reproductive toxicity studies have been conducted on cocoamidopropyl betaine. However, there was no evidence of an adverse effect on the reproductive organs in rats given oral doses of up to 1,000 mg/kg/day of a 30% aqueous solution of cocoamidopropyl betaine (300 mg active substance/kg/day) for 90 days (Th. Goldschmidt AG, 1991).

Developmental Toxicity

A 28.9% aqueous solution of cocoamidopropyl betaine was tested in a rat developmental toxicity at doses of 330, 990, and 3,300 mg/kg/day (corresponding to 95, 286, and 950 mg/kg/day, respectively) (CESIO, 2004). There were dose-related maternal toxic effects (reduced body weights and stomach ulcers) at 990 mg/kg/day and above. Embryotoxic effects (increased numbers of resorptions, decreased number of viable fetuses, decreased fetal body weight) were found only at the maternal toxic dose level of 3,300 mg/kg/day. The NOAEL for maternal toxicity was 330 mg/kg/day (corresponding to 95 mg active substance/kg-day) and the NOAEL for developmental toxicity was 990 mg/kg/day (corresponding to 286 mg active substance/kg/day).

Key Study/Critical Effect for Screening Criteria

The key study is a 90-day rat oral gavage study in which forestomach lesions were seen at dose levels of 500 and 1,000 mg/kg of a 30% aqueous solution of cocoamidopropyl betaine. The NOAEL was 250 mg/kg (75 mg active substance/kg).

$NOAEL_{adjusted}$ = 75 * 5/7 = 53.6 mg/kg/day

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 53.6/1000 = 0.05 mg/kg/day

Drinking water guideline = 0.19 ppm

Toxicity Profile

Hydrochloric acid
(CAS No. 7647-01-0)

Hydrochloric acid has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Hydrochloric acid (HCl) or hydrogen chloride is readily dissociated in water into hydrated protons and chloride ion.

Acute Toxicity

The oral LD_{50} value of hydrogen chloride is reported to be 238 to 277 mg/kg for female rats (Hoechst AG, 1966), and 900 mg/kg for rabbits (Loewy and Munzer, 1923). The lethal dose by dermal exposure is >5,010 mg/kg for rabbits (Monsanto, 1976). The LC_{50} values for HCl are reported to be 23.7 - 60.9 mg/L/5min, 5.7- 7.0 mg/L/30min and 4.2 4.7 mg/L/60min for rats; and 20.9 mg/L/5min, 3.9 mg/L/30min and 1.7 mg/L/60min for mice (Darmer *et al.*, 1974; Hartzell *et al.*, 1990; MacEwean *et al.*, 1974).

Irritation

Concentrations >3.3% cause skin irritation, and concentrations >17% cause corrosion in animal studies (OECD, 2002a,b). An aqueous solution (4%) of hydrogen chloride was slightly irritating (Agner and Serup, 1988), and a 10% solution was determined to be 'Irritating to skin' for the EU Dangerous Preparations Directive, in human volunteer experiments (York *et al.*, 1996).

0.1 mL of 10% aqueous solution of HCl was highly irritating to the eyes of rabbits (Jacobs, 1992); 0.03 mL or more of 5% HCl was corrosive to the eyes of rabbits (Griffith *et al.*, 1980); 0.1 mL of a 3.3% aqueous solution of HCL was slightly irritating the eyes of rabbits (Hoechst AG, 1966); and 0.1 mL of a 0.33% aqueous solution of HCl was not irritating to the eyes of rabbits. (Hoechst AG, 1966).

Sensitization

Hydrogen chloride is not a skin sensitizer to guinea pigs and humans (Gad *et al.*, 1986).

Repeated Dose Toxicity

Rats were fed diets containing 280 to 1,250 mmol/kg hydrochloric acid (10.2 to 45.6 mg/kg) for 7-12 weeks. There was increased water intake in all treated groups. All

animals fed diet containing 937 mmol/kg and above for 9 weeks, and half of the animals fed diet containing 900 mmol/kg for 12 weeks died. Also at doses ≥937 mmol/kg, there was decreased body weight, food consumption, blood pH, femur length, rate of ash in bone (Upotn and L'Estrange, 1977). In another study with rats, hydrochloric acid was administered via drinking water at pH 2-3 (study duration not provided). Decreased protein levels in urine and decreased urine volumes were observed in the treatment groups (Clausing and Gottschalk, 1989).

Genotoxicity

While consistent negative results have been obtained in the bacterial systems, positive results have been obtained in the non-bacterial systems (OECD, 2002a,b). The positive results were observed at high concentrations, but they were considered to be artifacts due to the low pH. Positive results were obtained in a sex-linked recessive lethal study with *D. melanogaster*; only one dose level was tested (Stumm-Tegethoff, 1966) There are no mammalian studies on *in vivo* mutagenicity with hydrogen chloride

Carcinogenicity (Oral Studies only)

A ten-month study has been conducted using mice (Dyer *et al.*, 1946). Because the methods such as strain used, duration and dose of administration, presence of co-administration substance, were not appropriate, it cannot be used for the assessment of carcinogenicity of hydrochloric acid.

Reproductive Toxicity

No reliable studies were identified by the oral route.

Developmental Toxicity

No reliable studies were identified by the oral route.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for pH may apply to hydrochloric acid.

Toxicity Profile

2-Propanol or Isopopranol
(CAS No. 67-63-0)

Acute Toxicity

The acute oral LD_{50} has been reported as 4,700 mg/kg, 5,300 mg/kg, 5,500 mg/kg, and 5,8400 mg/kg in rats; 4,500 mg/kg in mice; and 5,030 mg/kg, 7,800 mg/kg, and 7,900 mg/kg in rabbits (31, 272, 274, 275, 144, 35 Kimura et al., 1971; WHO, 1990; Smyth and Carpenter, 1948; Lehman and Chase, 1994; Munch and Schwartze, 1925; Munch, 1972). The acute dermal LD_{50} in rabbits has been reported to be 12,900 mg/kg (Smyth and Carpenter, 1948). The acute inhalation 8-h LC_{50} in rats was 19,000 ppm in females and 22,500 ppm in males (Laham *et al.*, 1980). Exposure of rats to 16,000 ppm for 8 h resulted in four deaths out of six animals (Smyth and Carpenter, 1948).

Irritation

Isopropanol applied to the intact or abraded skin of rabbits and guinea pigs produced negligible irritation (Nixon *et al.*, 1975). Liquid isopropanol is moderately irritating to the eyes of rabbits (Griffith *et al.*, 1980; WHO, 1990). Isopropanol produced little irritation when tested on the skin of six human subjects (Bevan, 2012).

Sensitization

There have been reports of isolated cases of dermal irritation and/or skin sensitization (Bevan, 2012). Except for three case reports, the positive reactions were observed on patch testing patients with contact dermatitis due to ethanol. These patients also had a positive reaction to ethanol.

Repeated Dose Toxicity (Oral Studies only)

In a drinking water study, rats ingested 0.5 to 10% of isopropanol for 27 weeks and showed decreased body weight gain but no gross or microscopic tissue abnormalities (Lehman and Chase, 1975). Increased formation of hyaline droplets in the proximal tubules was reported in male rats given 1–4% isopropanol in drinking water for 12 weeks (Pilegaard and Ladefoged, 1993). In another study, daily application of a 50% solution to the heads of rats for 187 days produced no apparent injury to the skin (Boughton, 1944). Isopropanol was administered in drinking water to three dogs for 7 months. The alcohol concentration was 4% from the end of the first month until the conclusion of the experiment. Tolerance to the alcohol developed as manifested by an increased degree of neuromuscular coordination at similar blood levels in habituated versus control animals

and by increased elimination of the alcohol. The only significant histopathological changes were noted in the kidneys of one dog that died (Lehman *et al.*, 1945).

Genotoxicity

All genotoxicity assays conducted so far with isopropanol have been negative (OECD, 1997a,b; Bevan, 2012). Isopropanol was not mutagenic in the *Salmonella* microsomal assay using the spot test, in strains TA98, TA100, TA1535, and TA1537 with and without S9 from the livers of Aroclor-induced rats (Abbondandolo *et al.*, 1980). Isopropanol was not mutagenic in *Salmonella* strains TA97, TA98, TA100, TA102, TA104, TA1535, TA1537, and TA1538 with and without metabolic activation, when tested using a plate-incorporation modification of this assay (Zeiger *et al.*, 1992).

Isopropanol was inactive in mutagenicity tests in *Neurospora crassa* (Brockman *et al.*, 1984) and isopropanol did not enhance adenovirus (SA7) transformation using Syrian hamster embryo cells (Heidelberger *et al.*, 1983). Isopropanol was inactive in a sister chromatid exchange assay with and without S9 metabolic activation (von der Hude *et al.*, 1987). Isopropanol was inactive in an *in vitro* CHO/HGPRT gene mutation assay and in an *in vivo* bone marrow micronucleus assay in mice (Kapp, Jr. *et al.*, 1993).

Carcinogenicity

No carcinogenicity studies have been conducted by the oral route.

CD-1 mice were exposed by inhalation to 0, 500, 2500, or 5000 ppm of isopropanol vapor for 6 h/day, 5 days/week for 18 months. An additional group of mice (all exposure levels) were assigned to a recovery group which were exposed to isopropanol for 12 months and then retained until study termination at 18 months. There was no increased frequency of neoplastic lesions in any of the isopropanol-exposed animals. Nonneoplastic lesions were limited to the testes (males) and the kidney. In the testes, enlargement of the seminal vesicles occurred in the absence of associated inflammatory or degenerative changes. The kidney effects included tubular proteinosis and/or tubular dilatation. The incidence of testicular and kidney effects was not increased in the isopropanol-exposed recovery animals (Burleigh-Flayer *et al.*, 1997).

Fischer 344 rats were exposed to 0, 500, 2500, or 5000 ppm of isopropanol vapor for 6 h/day, 5 days/week for 24 months. The mortality rates for all male rats were 82, 83, 91, and 100% for the 0-, 500-, 2500-, and 5000-ppm groups, respectively. The corresponding values for the female rats were 54, 48, 55, and 69%. The main cause of death for the 5000-ppm rats (both sexes), as well as for much of the mortality of the 2500-ppm male rats, was chronic progressive nephropathy. Isopropanol exposure resulted in impaired kidney function, as indicated by various urine chemistry changes in male (2500- and 5000-ppm) and female (5000-ppm) rats. Animals in these groups also exhibited histopathological effects in the kidneys which appeared to be an exacerbated form of

chronic progressive nephropathy. The only neoplastic lesion noted was increased interstitial (Leydig) cell adenomas in male rats. The frequency of these tumors, although elevated above the control animals, was within the historical control range of the testing facility and within the range reported for control animals from the National Toxicology Program carcinogenicity studies (Burleigh-Flayer *et al.*, 1997).

The carcinogenic potential of isopropanol was evaluated via inhalation using three strains of mice. Male mice were exposed to 7.5 ppm of isopropanol for 3 to 7 h/day, 5 days/week for 5 to 8 months. Animals were killed at either 8 or 12 months. There was no significant increase in the number of lung tumors observed. Similarly, no increases in lung tumors were observed in the same strains of mice that received subcutaneous injections of isopropanol once weekly for 20 to 40 weeks (Weil *et al.*, 1952).

Reproductive Toxicity

In a two-generation reproductive toxicity study, Sprague–Dawley rats were dosed by oral gavage with 0, 100, 500, or 1,000 mg/kg isopropanol. There were seven parental deaths that were considered treatment-related: two high-dose F_0 females, two F_1 high-dose females, one mid-dose F_0 female, and two low-dose F_1 males. Lactation body weight gain was increased in the 500- and 1000-mg/kg females in both generations, and liver and kidney weights were increased in the 500- and 1,000-mg/kg groups in both sexes. Centrilobular hepatocyte hypertrophy was noted in some 1,000 mg/kg F_1 males. There were some kidney effects in the 500- and 1000-mg/kg F_0 males and in all treated F_1 male rats. The kidney effects were characterized by an increased number of hyaline droplets in the convoluted proximal tubular cells, epithelial degeneration and hyperplasia, and proteinaceous casts. Increased mortality occurred in the high-dose F_1 offspring during the early postnatal period; no other clinical signs of toxicity were observed in the offspring from either generation. Offspring body weight, however, in the 1,000-mg/kg group was reduced during the early postnatal period. There was significant mortality in the F_1 weanlings (18/70) before the selection of the F_1 adults. A statistically significant reduction was observed in the F_1 male mating index of the 1,000-mg/kg group (73 versus 97% in the controls). There were no other treatment-related effects on reproduction, including fertility and gestational indices, or histopathology of the reproductive organs (Bevan *et al.*, 1995). A benchmark dose level of 420 mg/kg/day (lower bound on dose associated with a 5% response rate for the decrease in the male mating index was calculated (Allen *et al.*, 1998).

In a one-generation reproductive/embryotoxicity study, male and female Wistar rats were given 0, 0.5%, 1.0% or 2.0% isopropanol in their drinking water. The calculated intakes for males were 383, 686 and 1107 mg/kg-day (pre-mating) and 347, 625 and 1030 mg/kg-day (18 weeks of treatment). The calculated intakes for females were 456, 835 and 1206 mg/kg-day (premating); 668, 1330 and 1902 mg/kg-day (gestation); and 1053, 1948 and 2768 mg/kg-day (postpartum). An immediate, statistically significant dose-dependent decrease occurred in water intake in the male rats. Intake was reduced ~5-14% (1% group; premating period) and ~30% (2% group; days 7-11 to end of study).

Overall mean feed consumption was significantly lower in treated versus control animals. Male body weights (2% only) were reduced throughout the study. Water consumption was initially reduced in the 1% and 2% females, but the 2% group recovered to only ~70% of the control values (premating); it continued to be reduced during the gestation and lactation period. Mean maternal body weights were reduced (all treated groups) at the start of gestation, with partial recovery during the gestation period except for the 2% group. Overall weight gain during gestation in these groups were similar to the controls. Following parturition from PND 4 onward, the 2% dams had significantly lower body weights. There were no infertile males in any group, and no treatment-related effect on female fertility or on length of gestation. The number of pups/litter on GD 1 was reduced in the 2% group; because it was not replicated in the embryotoxicity portion, an increase in pup mortality during partuition or GD 0, followed by cannibalism of the dead pups by the dam was suggested. No macroscopic abnormalities were seen in females; nor was there any treatment-related histopathological changes seen in the reproductive tissue in the 2% parental animals. Absolute kidney weight and relative kidney, liver, and spleen weights were increased in the 2% F0 males; increased absolute liver and kidney weights and relative liver weights in the 2% F0 females. In the embryotoxicity portion, there was a statistically significant increase in the total number of preimplantation losses in the 2% animals. Whole body edema was seen in 40% of the fetuses in 3/8 litters in the 2% group. No macroscopic abnormalities of the viscera of these fetuses were detected, and the incidence of edema was not related to gender. In the one-generation portion, postnatal pup survival and in the average pup weight (by PND 7) were decreased in the 2% group. F1 generation animals of both sexes showed increased relative liver weights at all dose levels, and the 2% males had higher relative kidney weights. A slight but significant decrease in absolute brain weight and increase in relative empty cecum weights in both sexes of the 2% F1 generation group. No treatment-related gross abnormalities were observed in the F1 generation animals at necropsy (BIBRA, 1988).

The effects of isopropanol (2.5% in drinking water) on the reproduction and growth of rats was assessed in a multigenerational study. No reproductive toxicity was observed (Lehman *et al.*, 1945).

Isopropanol was administerd as a 3% solution in drinking water to Wistar rats. Reduced parental body weight gain, food, and water consumption was observed in the treated animals compared with the controls. Fertility, litter size, and pup weights at postnatal days 4 and 21 were reduced in treated animals compared with the controls. In the second generation, the isopropanol concentration was reduced to 2%, and there were essentially no effects (Gallo *et al.*, 1977).

Developmental Toxicity

Isopropanol was given at concentrations of 0, 0.5%, 1.25% or 2.5% in the drinking water to female Wistar rats on GD 6 to 16. The calculated intakes of isopropanol during GD 6-16 were 596, 1242 and 1605 mg/kg/day. There was an immediate reduction in water intake in the 2.5% dose group, and this was statistically significant throughout the

treatment period when compared to controls. A smaller reduction in water intake was also seen in the 1.25% females (statistically significant during GD 6-9), with no change in the 0.5% females. Palatability of the drinking water may have been the problem since water intake significantly increased the first day following the end of the treatment period for all dose groups. Feed consumption patterns paralleled the water consumption during and after treatment in the mid- and high-dose groups. Overall, mean body weights of the 2.5% females were lower than the controls from GD 7 to termination. Effects on weight gain in the 0.5% and 1.25% females were limited to a failure to gain weight during the first (0.5%) and second (1.25%) day of treatment. There were no treatment-related effects in postimplantation loss, mean number of implantation sites or live fetuses. There was a slight dose-dependent decrease in mean litter weight and a significant decrease in mean fetal weight in the 1.25% and 2.5% groups. A statistically significant increase in variations was observed, indicative of a lower degree of ossification in the treated animals There was a dose-dependent decrease in the number of fetuses with the 4^{th} sacral arch and a dose-dependent increase in the number of fetuses with less than 2 caudal arches. The sternum also showed reduced ossification because there were increased numbers of fetuses with small, absent, or incompletely ossified sternebrae (BIBRA, 1987).

In a rat developmental study, female Sprague–Dawley rats were dosed by oral gavage with either 0, 400, 800, or 1200 mg/kg of isopropanol during gestational days 6 to 15. Two dams (8%) died at 1200 mg/kg and one dam (4%) died at 800 mg/kg. At 1200 mg/kg, maternal body weights were reduced throughout gestation (GS 0-20; 89.9% of control value), associated with reduced gravid uterine weight. There were no other treatment-related effects on the dams. Fetal body weights per litter were also significantly reduced at the 800 and 1200 mg/kg dose levels, but there were no teratogenic effects. There were no adverse maternal or developmental effects at 400 mg/kg (Tyl *et al.*, 1994).

In a rabbit developmental study, female New Zealand white rabbits were dosed by oral gavage with either 0, 120, 240, or 480 mg/kg of isopropanol during gestational days 6 to 18. At 480 mg/kg, isopropanol was unexpectedly toxic to pregnant female rabbits, resulting in the deaths of four does (26%). Maternal body weights were significantly reduced during treatment (gestational days 6–18) and were associated with reduced maternal food consumption during this period. Profound clinical signs were noted at 480 mg/kg and included flushed and/or warm ears, cyanosis, lethargy, and labored respiration. No adverse maternal effects were noted at 120 or 240 mg/kg. There were no developmental or teratogenic effects at any dose tested (Tyl *et al.*, 1994).

Isopropanol was given by oral gavage to Sprague–Dawley rats from gestational days 6 to 21 in doses of 0, 200, 700, or 1200 mg/kg. The dams were allowed to deliver, litters were culled on postnatal day (PND) 4, pups were weaned on PND 22, and their dams were killed. Weaned pups were assessed for day of testes descent or vaginal opening, motor activity, auditory startle, and active avoidance. The pups were killed on PND 68. Some of the pups were taken from each dose group and were perfused in situ for pathological examination of the central nervous system. There were no biologically significant findings in the behavioral tests, no changes in organ weights, and no pathological

findings of note. Thus, there was no evidence of developmental neurotoxicity from isopropanol exposure (Bates *et al.*, 1994).

Key Study/Critical Effect for Screening Criteria

The benchmark dose level of 420 mg/kg/day from the two-generation reproductive toxicity study will be used to derive a drinking water guidance value for 2-propanol.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral Reference Dose = 420/100 = 4 mg/kg/day

Toxicity Profile

Magnesium chloride
(CAS No. 7786-30-3)

Acute Toxicity

The oral LD_{50} of magnesium chloride hexahydrate in rats is >2,000 mg/kg. The dermal LD_{50} of magnesium chloride hexahydrate in rats is >2,000 mg/kg.

Irritation

Magnesium chloride hexahydrate was applied topically to the EPISKIN-SMätissue for 15 min followed by a 42 hour post-incubation period and immediate determination of cytotoxic effects via MTT reduction assay. The test item showed no irritant effects.

Single ocular instillation of magnesium chloride hexahydrate to rabbits at a dose of 0.1 g produced irritant effects, which were fully reversible within 6, 4 and 2 days post-instillation in animal no. 1, 2 and 3, respectively. Based on these findings, magnesium chloride hexahydrate is not an eye irritant.

Sensitization

Magnesium chloride hexahydrate was not a skin sensitizer when tested in guinea pigs.

Repeated Dose Toxicity

In an OECD 422 study, Wistar rats at dosages of 250, 500 and 1,000 mg/kg magnesium chloride hexahydrate revealed no major toxicological findings. The cause of death of animals during the conduct of the study could not be determined (a plausible cause may be gavage error or regurgitation). The NOAEL for this study is 1,000 mg/kg/day.

Groups of 50 male and 50 female $B6C3F_1$ mice were given magnesium hexahydrate at dose levels of 0, 0.5% and 2% in the diet for 96 weeks, after which all animals received the control diet for 8 weeks and were then necropsied. In the 2% females, a decrease in body weight was observed. However, survival rates did not differ between the treatment and control groups for males or females and clinical signs and urinary, hematological or serum clinical chemistry parameters showed no treatment-related effects. Therefore, this change was considered not to be of biological significance. The NOAEL for female and male mice was 2% in feed, which corresponded to 3,930 and 2,810 mg/kg/day, respectively.

Genotoxicity

Magnesium chloride was not genotoxic in the *in vitro* mouse lymphoma assay and in the *in vitro* chromosomal aberration assay using human lymphocytes.

Carcinogenicity

Male and female $B6C3F_1$ mice were given in their fed 0, 0.5% or 2% magnesium chloride hexahydrate for 96 weeks, after which all animals received the control diet for 8 weesk and were then necropsied. Tumors were mainly found in the skin/subcutis, liver and lymphatic system. With the exception of a significant decrease in the incidence of liver tumors among the 2% males, there were no differences in the tumor incidences between the treated and control animals.

Reproductive/Developmental Toxicity

In an OECD 422 study, Wistar rats at dosages of 0, 250, 500 or 1,000 mg/kg showed no treatment-related reproductive or developmental effects. The NOAEL for this study is 1,000 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guideline value for chloride may apply to magnesium chloride.

ECHA REACH database: http://apps.echa.europa.eu/registered/registered-sub.aspx

Toxicity Profile

Magnesium nitrate
(CAS No. 10377-60-3)

Acute Toxicity

The acute oral LD_{50} in rats is >5,000 mg/kg.

Irritation

No studies are available.

Sensitization

Magnesium nitrate is not a skin sensitizer based on results of a Local Lymph Node Assay (LLNA).

Repeat Dose Toxicity Studies

No studies are available.

Genotoxicity

Magnesium nitrate hexahydrate is not mutagenic in the *Salmonella typhimurium* reverse mutation assay and in the *Escherichia coli* reverse mutation assay.

Carcinogenicity

No data are available.

Reproductive Toxicity

No data are available.

Developmental Toxicity

No data are available.

Key Study/Critical Effect for Screening Criteria

The Australian drinking water guidance value for nitrates may apply to magnesium nitrate.

Benzenesulfonic acid, 4-ethyenyl-, sodium salt, homopolymer
(CAS No. 25704-18-1)

Acetic acid ethenyl ester, polymer with ethanol
(CAS No. 25213-24-5)

Vinylidene chloride/methacrylate copolymer
(CAS No. 25038-72-6)

Polyvinyl acetate, partially hydrolyzed
(CAS No. 30443-60-5) THIS IS NOT THE CORRECT CASRN

All of the these substances are polymers.

Mammalian toxicity data was located for only for acetic acid, ethenyl ester, polymer with ethanol (CAS No. 25213-24-5) on a supplier's MSDS. However, all of the polymers listed above are expected to exhibit similar toxicity profiles.

As polymers, they are not expected to be absorbed by the oral, dermal or inhalation routes of exposure due to their large molecular weights. They are also expected to be stable in biological media and resistant to metabolism.

This polymers are expected to be essentially acutely non-toxic by the oral, dermal and inhalation routes of exposure. The oral LD_{50} in rats for CAS No. 25213-24-5 was reported to be >11,000 mg/kg. Under certain conditions, dusts may be formed, which is to be considered as a nuisance dust. The polymers are expected to be non-irritating and not dermal sensitizers. No irritation or sensitization was observed in guinea pigs from CAS No. 25213-24-5.

These polymers are not expected to exhibit any systemic toxicity.

Reference

DuPont (2006). MSDS for "ELVANOL" 60-30, revised 27-Oct-2006.

Toxicity Profile

Sodium chloroacetate
(CAS No. 3926-62-3)

Sodium chloroacetate has been reviewed in the OECD-SIDS program (OECD, 1994).

Acute Toxicity

The oral LD_{50} is 76 mg/kg in rats (Woodard *et al.*, 1941); 165 mg/kg (Morrison, 1946) and 225-339 mg/kg (Woodard *et al.*, 1941) in mice; and 79 mg/kg in guinea pigs (Woodard *et al.*, 1941). The dermal LD_{50} is >2,000 mg/kg in rats (Hofmann and Jung, 1988).

A number of cattle died after accidental exposure to sodium chloroacetate. The doses involved were at least 17 to 70 mg/kg and probably in the order of 170 mg/kg. Extensor paralysis of the limbs, tremors, and convulsions were observed in three cows before death (Quick *et al.*, 1983). In cows exposed to 50 mg/kg, lethargy lasting 24 hours was observed. A doubling of the dose resulted in severe symptoms of intoxication (diarrhea, muscular twitching and loss of muscle tone) with recovery after two weeks. Death occurred within nine hours later (Dalgaard-Mikkelsen and Rasmussen, 1961).

Irritation

When tested in an OECD 404 guideline study, 500 mg of sodium chloroacetate was not irritating to the skin of rabbits (Kreling and Jung, 1988). When tested in an OECD 405 guideline study, 100 mg of sodium chloroacetate was not irritating to the eyes of rabbits (Kreiling and Jung, 1988).

Sensitization

No data are available.

Repeated Dose Toxicity

Sprague-Dawley rats (10/sex/dose) were dosed by oral gavage with 0, 15, 30, 60 or 120 mg/kg sodium chloroacetate for 90 consecutive days. At 120 mg/kg, 30% of the females and 80% of the males died within the first two days of treatment. Hemorrhagic and congested lungs (possibly a postmortem change) were observed in early deaths (1-3 days), whereas liver lesions were observed in later deaths. The levels of creatine, blood calcium and blood urea nitrogen were significantly elevated in males in all dose groups, but creatine levels were elevated in the 30 and 60 mg/kg females. Increased serum levels

of alanine aminotransferase and separate aminotransferase were seen in both males and females, but a significant trend could not be demonstrated. Chronic heart inflammation was present in both sexes, particularly at the higher dose levels. Relative liver and kidney to bodyweight ratios were increased in both sexes. Histopathological examination showed a significant increase in chronic renal nephropathy and increased splenic pigmentation in the 60 mg/kg males.

Chronic progressive nephropathy (CPN) is a common spontaneous kidney disease of laboratory rat strains (Gray, 1977) that is both a degenerative and regenerative entity exhibiting a high rate of tubule cell proliferative activity throughout its progression (Hard and Khan, 2004; Short *et al.*, 1989). It is a progressive disease with known physiological factors that modify disease progression, such as high dietary protein. Hard et al. (2009) compared CPN in rats and human nephropathies and concluded that CPN is a distinctive entity in rats with no counterpart in human disease. A number of chemicals have been shown to exacerbate CPN in rats, particularly in Sprague-Dawley rats (Hard et al., 2012). Because of the uniqueness of CPN to rats, the chemical-induced exacerbation of CPN in male rats should not be considered relevant to human health risk assessments (Hard et al., 2012)

Thus, the LOAEL for this study is considered to be 60 mg/kg/day based on the increased incidence of splenic pigments, brown and localized in splenic macrophages, which were statistically significant in the 60 mg/kg/day male rats. The NOAEL is 30 mg/kg/day.

Genotoxicity

No data are available.

Carcinogenicity

No data are available.

Reproductive Toxicity

No data are available.

Developmental Toxicity

An unpublished study was cited in the OECD-SIDS dossier on chloroacetate (OECD, 2004). Female rats were dosed with 0, 17, 35, 70 or 140 mg/kg sodium chloroacetate during GD 6-15. Mean adjusted percentage weight gain for GD 0 to 20 was reduced in the 140 mg/kg dams. Reduction in weight gain was also observed in the 35, 70 and 140 mg/kg groups for the first three days of dosing. Mean cardiovascular malformations,

comprising of levocardia, were significantly elevated over controls for the 140 mg/kg group. The mean frequency per litter of soft tissue malformations ranged from 1.2% (controls) to 6.37% (140 mg/kg); there was no dose-related effect. The NOAELs for maternal and developmental effects were 70 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

A 90-day rat oral gavage toxicity study was conducted. The LOAEL for this study is considered to be 60 mg/kg/day based on the increased incidence of splenic pigments, brown and localized in splenic macrophages, which were statistically significant in the 60 mg/kg/day male rats. The NOAEL is 30 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral Reference Dose = 30/1,000 = 0.03 mg/kg/day

Drinking water guideline value = 0.11 ppm

Toxicity Profile

Talc
(CAS No. 61789-40-0)

Talc refers to both mineral talc and industrial mineral products that are marketed under the name talc and contain proportions of mineral talc that range from about 35% to almost 100%. Industrial talc generally refers to products that contain abundant minerals other than talc; cosmetic talc now normally contains >98% talc but the content may have been lower in the past. Pharmaceutical talc contains >99% talc. Talcum powder is cosmetic-grade talc.

Talc is a mineral composed of hydrated magnesium silicate with the chemical formula $Mg_3Si4O_{10}(OH)_2$ or $H_2Mg_3(SiO_3)_4$. Talc is not soluble in water.

The U.S. Food and Drug Administration (FDA) regulates talc and states that it is generally recognized as safe for use in color additives in foods, drugs and cosmetics, and in paper, paper products, cotton and cotton fabrics that come into contact with food. The Food Chemical Codex (2003) provides specifications for food-grade talc, including the statement that "talc derived from deposits that are known to contain associated asbestos is not food grade." Under the voluntary guidelines initiated in 1976, the Cosmetic, Toiletry, and Fragrances Association stated that all cosmetic talc should contain at least 90% platy talc (hydrated magnesium silicate) that is free from detectable amounts (<0.5%) of fibrous, asbestos minerals.

Toxicokinetics (Oral)

The absorption and disposition of ^{3}H-labeled talc in rats, mice, and guinea pigs administered a single oral dose was studied by Phillips *et al.* (1978). The oral doses were 50 mg/kg for rats, 40 mg/kg for mice, and 25 mg/kg for guinea pigs. In rats, mice, and guinea pigs, more than 95% of the dose was excreted in the feces 3 to 4 days after dosing. Less than 2% of the radioactivity was recovered in the urine. This radioactivity probably reflected contamination of urine samples with feces. No radioactivity was found in the liver or kidneys of these animals. This information suggests that talc is not absorbed from the gastrointestinal tract following oral exposure.

Acute Toxicity

No data were located.

Repeated Dose Toxicity/Carcinogenicity

Male and female Wistar rats were given in their diet 0 or 50 mg/kg of commercial talc [characteristics unspecified] for the life of the animals (average survival was 702 and 649 days, respectively). There was no significant difference in the talc-fed animals compared with control animals (Gibel *et al.*, 1976).

Male and female Wistar-derived rats were given in their diet 100 mg Italian talc (grade 00000; ready milled; mean particle size, 25 μm; containing 92% talc, 3% chlorite, 1% carbonate minerals and 0.5–1% quartz) per rat per day for 5 months (talc-containing diet was actually given for 101 days) and were then maintained on basal diet for life (average survival, 614 days). No differences in tumor incidence were noted between treated animals and control animals (eight/sex for an average survival of 641 days) (Wagner *et al.*, 1977).

In humans and experimental animals, the effects of talc are dependent on the route of exposure, and the dose and properties of the talc. Talc pneumoconiosis was somewhat more prevalent and severe among miners exposed to talc containing asbestiform minerals and/or asbestos than among those exposed to talc without such contaminants. However, the role of quartz and asbestos in the observed pneumoconiosis could not be ruled out. Among drug users, intravenous injection of talc present as a filler in the drugs resulted in microembolization in a variety of organs and alterations in pulmonary function. In animal studies, talc has been shown to cause granulomas and mild inflammation when inhaled. Observations of the effects that occurred in the lungs of rats exposed by inhalation to talc suggested that the operative mechanisms may be similar to those identified for carbon black, and talc is known to cause the release of cytokines, chemokines and growth factors from pleural mesothelial cells.

IARC: There is *inadequate evidence* in humans for the carcinogenicity of inhaled talc not containing asbestos or asbestiform fibres. There is *limited evidence* in experimental animals for the carcinogenicity of talc not containing asbestos or asbestiform fibres. Inhaled talc not containing asbestos or asbestiform fibres is *not classifiable as to its carcinogenicity (Group 3).*

Genotoxicity

The IARC (1987) review of talc included unpublished results from a 1974 study conducted by Litton Bionetics that showed no mutagenic activity for talc *in vitro* or *in vivo.* Talc did not induce mutations in *Salmonella typhimurium* strains TA1530 or HisG46, or in the yeast, *Saccharomyces cerevisiae.* No chromosomal aberrations were observed in human fibroblasts treated with talc *in vitro. In vivo* tests conducted in rats gave negative results for induction of chromosomal aberrations in bone marrow cells and dominant lethal mutations in germinal cells.

Three samples of respirable talc failed to elicit significant unscheduled DNA synthesis (10, 20 and 50 μg/cm^2, 24 hours), sister chromatid exchange or aneuploidy (2, 5, 10 and 15 μg/cm^2, 48 hours) in rat pleural mesothelial cells, in contrast to various positive controls. The three samples, *i.e.* Spanish talc (No. 5725), Italian talc (No. 5726) and French talc (No. 7841), contained 90–95% talc; the remaining contents were chlorite and dolomite. Electron microscopy analysis revealed that talc particles were taken up by the rat pleural mesothelial cells, but no aneuploidy was observed in metaphases (Endo-Capron *et al.*, 1993).

Reproductive Toxicity

No data are available.

Developmental Toxicity

No teratologic effects were observed in hamsters, rats, mice, or rabbits after oral administration of talc. The doses used were 1,600 mg/kg for rats and mice on days *6* through 15 of gestation; 1,200 mg/kg for hamsters on day 6 through 10 of gestation; and 900 mg/kg for rabbits on days 6 through 18 of gestation.

Key Study/Critical Effect for Screening Criteria

There are no adequate studies for which to derive a oral reference dose. Talc is poorly absorbed from the gastrointestinal tract, if at all, and the limited data available by the oral route indicate that talc is essentially non-toxic by the oral route of exposure.

Toxicity Profile

Tetramethylammonium chloride
(CAS No. 75-57-0)

Surrogates:
Didecyldimethylammonium chloride
(CAS No. 7173-51-5)
Dodecyltrimethylammonium chloride
(CAS No. 112-00-5)

No data could be located on tetramethylammonium chloride. Toxicity data are available for didecyldimethylammonium chloride (DDAC) and dodecyltrimethyl-ammonium chloride (DTAC). Thus, these two substances have been used as surrogates for the alkylated quaternary chloride.

Acute Toxicity

The oral LD_{50} of 100% DDAC has been reported to be 84 mg/kg in rats and 268 mg/kg in mice. The oral LD_{50} of a 5-25% solution of DDAC in rats was reported to be 1,190 mg/kg (595 to 297 mg a.i./kg). The acute dermal LD_{50} of a 80% solution of DDAC in rats is 3,342 mg/kg (2674 mg a.i./kg).

The acute oral LD_{50} of DTAC (24.7% aq. soln.) in rats is 490 mg/kg. The acute oral LD_{50} of DTAC (37.35% aq. soln.) in rats is 560 mg/kg.

Irritation

DDAC is a severe skin and eye irritant to rabbits.

Sensitization

DDAC is not a dermal sensitizer to guinea pigs or to humans.

Repeatd Dose Toxicity

Mice were given in their diet 0, 100, 300, 600, 1,000 or 3,000 ppm DDAC for 89-90 days. For the lowest four dose groups, these doses correspond to mean intake levels of approximately 18, 52, 107, and 182 mg/kg for males, and 23, 68, 134, and 224 mg/kg for females. High mortality in the 3,000 ppm groups prohibited calculation of daily intakes. Treatment of mice with 3,000 ppm DDAC in the diet for several days resulted in virtually

100% mortality in both sexes, with only one male surviving to termination of the study. Death was attributed to treatment-related severe wasting and dehydration resulting from gastrointestinal effects. Treatment with 1,000 ppm DDAC produced a 5% decrease in body weight in males with associated decreases in body weight gain. Similar depressed body weight in females from this group was assumed to be related to DDAC exposure. No other changes were observed in males or females in the other dose groups. The NOEL for this study is 600 ppm (107 and 134 mg/kg/day for males and females, respectively).

Rats were given in their diet 0, 100, 300, 600, 1,000 or 3,000 ppm DDAC for 89-90 days. For the lowest four dose groups, these doses correspond to mean intake levels of approximately 6, 18, 37, and 61 mg/kg for males, and 8, 22, 44, and 74 mg/kg for females. High mortality in the 3,000 ppm group prohibited calculation of mean daily intakes. Dietary exposure to 3,000 ppm DDAC resulted in 80% mortality in both sexes. The three rats of each sex of this group that survived to the end of the study exhibited markedly reduced body weights, fluid- or gas-filled intestines at necropsy, and inflammation of the beginning of the large intestines (typhlitis). Pathological changes in clinical chemistry included decreased serum glucose and protein concentrations in both sexes, decreased albumin and globulin concentrations in females, and increased erythrocyte count and hemoglobin and hematocrit concentrations in males. Administration of 1,000 ppm of less of DDAC resulted in no treatment-related effects. The NOEL for this study is 61 and 74 mg/kg/day for males and females, respectively.

Male and female beagle dogs were given DDAC in their diet at doses of 0, 5, 15 and 50 mg/kg for 90 days. There was marked decrease in body weight gain, food consumption and food efficiency in the 50 mg/kg dose group. Clinical chemistry, hematology, urinalysis, and pathological results did not reveal any treatment-related effects. The NOAEL for this study is 15 mg/kg/day.

Beagle dogs were dosed orally with 0, 3, 10, or 30 mg/kg DDAC for 52 weeks. During the first four and a half weeks of the study, several dogs in the 30 mg/kg group showed potentially life threatening decreases in body weight and food consumption. The dose was therefore decreased to 20 mg/kg/day. In some cases, depressions in weight and food consumption were so severe that the dogs in this group were removed from treatment completely during study days 31-36, and then reinstated at the 20 mg/kg/day. Administration of 3 or 20 mg/kg/day was not associated with mortality, changes in organ weights, gross pathological findings, ophthalmologic changes, or microscopic changes in selected organs and tissues. The 20 mg/kg/day dose was associated with decreases in mean erythrocyte counts; hemoglobin and hematocrit values; and mean total cholesterol, total protein, and albumin values. The 10 and 20 mg/kg/day doses were associated with an increased incidence of emesis, salivation, and soft/mucoid/liquid feces compared to controls. The NOEL for systemic toxicity was considered to be 10 mg/kg/day.

Sprague-Dawley rats were given in their diet 0, 300, 750, or 1,500 ppm DDAC for at least 104 weeks. These doses corresponded to approximate DDAC intakes of 13, 32, and 64 mg/kg/day for males, and 16, 41, and 83 mg/kg/day for females. Treatment-related

decreases in body weight and food consumption in both males and females were observed in the 1,500 ppm group. In addition, possible treatment-related microscopic changes including hyperplasia of bile ducts in female rats and changes in mesenteric lymph nodes in male and female rats related to blood in the sinuses were observed in the 1,500 ppm group. No treatment-related effects were seen in the type of incidence of clinical signs, survival, palpable masses, clinical pathology, organ weights, gross anatomic pathology, or ophthalmology. The NOEL for toxicity was considered to be 750 ppm (32 and 41 mg/kg/day for males and females, respectively).

CD-1 mice were administered in their diet 0, 100, 500, or 1,000 ppm DDAC for at least 78 weeks. The approximate mean intake levels were 15, 76.3, and 155.5 mg/kg/day for males and 18.6, 93.1, and 193.1 mg/kg/day for females. Treatment-related findings included decreased body weights and body weight gains in both male and females from the 1,000 ppm groups. There were no treatment-related clinical signs of toxicity, increases in palpable masses, changes in food consumption, differences in organ weights or observations at necropsy or differences in histopathological findings. The NOEL for this study was considered to be 500 ppm (76.3 and 93.1 mg/kg/day for males and females, respectively).

Genotoxicity

Several studies evaluating the mutagenicity of DDAC have all given negative results. DDAC was not mutagenic to several strains of *S. typhimurium* in a bacterial reverse mutation assay with or without metabolic activation. DDAC was tested in the CHO/HGPRT forward mutation assay and was not mutagenic in the presence or absence of metabolic activation. DDAC did not induce chromosomal aberrations in CHO cells with or without metabolic activation. In the *in vitro* rat primary hepatocyte unscheduled DNA synthesis (UDS) assay, DDAC did not induce significant increases in UDS. No chromosomal damage was observed in the bone marrow of rats in an *in vivo* cyogenetics assay.

DTAC (24.7% aq. soln.) was not mutagenic to bacteria in a reverse mutation assay with or without metabolic activation. DTAC (24.7% aq. soln.) was not mutagenic in a mouse lymphoma assay with or without metabolic activation. DTAC was inactive in a rat primary hepatocyte UDS assay. DTAC was not genotoxic when given by oral gavage in a rat bone marrow micronucleus assay.

Carcinogenicity

Sprague-Dawley rats received DDAC in their diet at concentrations of 0, 300, 750 or 1,500 ppm for at least 104 weeks. These doses corresponded to approximate mean DDAC intakes of 13, 32, and 64 mg/kg/day for males, and 16, 41, and 83 mg/kg/day for females. DDAC was not considered to be carcinogenic under the conditions of this study.

CD-1 mice were administered in the diet 0, 100, 500, or 1,000 ppm DDAC for at least 78 weeks. The approximate mean intake levels were 15, 76.3, and 155.5 mg/kg/day for males, and 18.6, 93.1, and 193.1 mg/kg/day for females. DDAC was not considered to be carcinogenic under the conditions of this study.

Reproductive Toxicity

A two-generation reproductive toxicity study has been conducted with DDAC. Sprague-Dawley rats were given in their diet 0, 300, 750 or 1,500 ppm for two generations. Results indicate that continuous exposure to DDAC in the diet for two generations resulted in no adverse reproductive effects. Parental toxicity was observed at 1,500 ppm (~112.6 mg/kg/day), limited to body weight reduction, weight gain depression, and decreased food consumption. Postnatal toxicity at 1,500 ppm was indicated by reduced pup body weights. Based on decreased body weight/weight gain and food consumption, the parental Toxicity NOAEL = 750 ppm (56 mg/kg/day); LOAEL = 1500 ppm (113 mg/kg/day). Based on decreased pup body weight/weight gain, the reproductive toxicity NOAEL = 750 ppm (56 mg/kg/day); LOAEL = 1500 ppm (113 mg/kg/day).

Developmental Toxicity

Female NZ rabbits were given by oral gavage 0, 1.0, 3.0 or 10 mg/kg/day of DDAC during GD 6-18. Four of the 16 does in the highest group died prior to GD 13. One doe at 10 mg/kg and 2 does at 1.0 mg/kg delivered early and were removed from the study. Nonlethal indications of maternal toxicity were evident at 3 and 10 mg/kg, as evidenced by reduced weight gain and clinical signs during the treatment period. Developmental toxicity, including increased incidences of fetal mortality and reduced fetal body weight per litter, were observed only at the highest dose. No teratogenicity was observed at any dose level. The NOEL for maternal toxicity is 1 mg/kg/day, and the NOEL for developmental toxicity is 3 mg/kg/day.

Female Sprague-Dawley rats were given by oral gavage 0, 1, 10 or 20 mg/kg DDAC during GD 6-15. No females died, aborted, delivered early, or were removed early from the study. Maternal toxicity was indicated at 10 and 20 mg/kg by characteristic clinical signs of audible respiration. Reductions in body weight and food consumption were also observed at 20 mg/kg during the treatment period. No evidence of developmental toxicity including teratogenicity was observed at any dose level. The NOEL for maternal toxicity was 1 mg/kg/day. The NOEL for developmental toxicity is >20 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The lowest NOAEL was 10 mg/kg/day for dogs in the one-year chronic toxicity study. The LOAEL of 20 mg/kg/day was based on increased incidence of clinical signs in males and females, and decreased total cholesterol levels in females.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral Reference Dose = 20/100 = 0.2 mg/kg/day

Drinking water guidance value = 0.7 ppm

APPENDIX F.5 HALLIBURTON ALTERNATIVE FLUID SYSTEM

Toxicity Profile

Acetic acid
(CAS No. 64-19-7)

Acetic acid dissociates in aqueous media to H^+ and the acetate anion ($CH_3CO_2^-$). It is naturally occurring as the acid in apple cider vinegar and other fruit-derived products. It and several of its salts are commonly used as food additives (*e.g.*, as flavor enhancers) and are listed as Generally Recognized as Safe (GRAS) by the U.S. Food and Drug Administration (FDA).

pH: 2.5 at 50 g/L and 20°C
pK_a: 4.76 @ 20°C

Acute Toxicity

The oral LD_{50} in rats is 4,950 mg/kg, and the dermal LD_{50} in rabbits is 1,060 mg/kg. The 4-hour LC_{50} in rats is 11.4 mg/L.

Irritation

In the EU, acetic acid is classified as a skin and eye irritant at concentrations <25%. At ≥25%, it is classified as corrosive to the skin.

Sensitization

No data are available.

Repeated Dose Toxicity

In an 8-month study, rats dosed with 60 mg/kg acetic acid (three times per week) developed hyperplasia in the esophagus and forestomach.

Genotoxicity

Acetic acid was not mutagenic to *Salmonella typhimurium* strains TA 98, TA 100, TA 1535, TA 1537, and TA 1538 in an *in vitro* bacterial mutation assay with or without metabolic activation. Acetic acid (in media adjusted to a pH of 8.5) was also not genotoxic in an *in vitro* chromosomal aberration test using Chinese Hamster Ovary cells with or without metabolic activation.

Carcinogenicity

No adequate carcinogenicity studies have been conducted on acetic acid.

Reproductive Toxicity

No studies could be located.

Developmental Toxicity

There were no effects on implantations or on maternal or fetal survival in mice, rats, or rabbits at doses up to 1,600 mg/kg.

Key Study/Critical Effect for Screening Criteria

There are no repeat dose toxicity studies that were considered adequate for human health risk assessment. The only study reported on the toxicity of acetic acid by oral gavage showed effects of irritation (probably due to the pH of acetic acid) at the site of contact in the gastrointestinal tract. No systemic effects were reported.

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) has maintained a group ADI of "not limited" for acetic acid and its potassium and sodium salts.

The Australian drinking water guidance value for pH may apply to acetic acid.

Toxicity Profile

Alcohols, C6-C12, Ethoxylated Propoxylated
(CAS No. 68937-66-6)

No toxicity information could located on alcohols, C6-C12, ethoxylated propoxylated (CAS No. 68937-66-6). Toxicity information is available on alcohol ethoxylates. Alcohols, C6-C12, ethoxylated propoxylated is produced by the use of propylene oxide (PO) in addition to ethylene oxide (EO) during the alkoxylation of the alcohol(s). the PO is either incorporated randomly by alkoxylation within the epoxide mixture, or in a block by sequencing the addition of EO and PO to the reactor. Because of the similarity in structures, the toxicity data on the alcohol ethoxylates were used to read-across to alcohols, C6-C12, ethoxylated propoxylated.

Alcohol ethoxylates are a class of non-ionic surfactants. The AEs have the basic structure $C_{x-y}AE_n$. The subscript (x-y) following the 'C' indicates the range of carbon chain units. AEs with carbon unit range between C8 to C18 are most commonly used in household detergent products. The hydrocarbon chain can be either linear or branched. AEs also contain an ethylene oxide (E) chain attached to the alcohol. The degree of ethylene oxide polymerization is indicated by the subscript (n) which indicates the average number of ethylene oxide units. In household products the average ethylene oxide chain length commonly ranges between 3 and 12 units.

The toxicity profile has been developed from a risk assessment report on alcohol ethoxylates ranging from C8 to C18 prepared by the household cleaning product and chemical industry (HERA, 2009).

Acute Toxicity

The acute oral LD_{50} of C9-11AE2.5 in rats was calculated to be >4,000 mg/kg and <10,000 mg/kg. The acute oral LD_{50} of C7-9AE6 in rats was determined to be <2,000 mg/kg. The acute oral LD_{50} of C9-11AE8 in fasted rats was found to be 1,200 mg/kg. The oral LD_{50} in rats for C12-13AE6.5 is 2,100 mg/kg. The oral LD_{50} in rats for C12-15AE7 is 1,700 mg/kg. For C14-15AE11, the acute oral LD_{50} values were reported to be 720 mg/kg (neat) and 1,800 mg/kg (given as 50% (m/v) solution in corn oil). The oral LD_{50} in rats for C12-15AE11 is >2,00 mg/kg for males and between 1,000 and 2,000 mg/kg for females. The oral LD_{50} in rats for C14-15AE13 is 1,100 and 1,000 mg/kg in two separate studies.

The dermal LD_{50} of C7-9AE6 was >2,000 mg/kg. The dermal LD_{50} values for AEs with an alkyl chain length of 9 – 11 carbon atoms in three different rat studies were determined to be >2,000 mg/kg and >4,000 mg/kg. An acute dermal LD_{50} value of >2,000 mg/kg was determined for C12-14AE3 and C12-14AE6 in two separate studies. The acute dermal LD_{50} of C12-15AE7 was determined to be >2,000 mg/kg.

The acute rat 4-hour LC_{50} of C9-11AE5 generated as a mist was determined to be >0.22 mg/L. Talmage (1994) reported that alcohol ethoxylates were not acutely toxic to rats at concentrations less than or equal to their saturated vapor concentrations in air. Acute toxic thresholds were reached only when animals were exposed to the undiluted test chemical in the form of a respirable mist or aerosol. Under these conditions, 1- or 4-hour inhalation LC_{50} values ranged from 1.5 to 20.7 mg/L. Some studies reported no mortalities (1-hour LC_{50} -study) occurred at concentrations as high as 52 mg/L.

Irritation

Alcohol ethoxylates with varying alkyl chain lengths and ethoxylation degree were found to be slightly to severely irritating to skin in rabbits and rats. The degree of irritation was dependent on the type of patches used (open application versus full occlusion), the exposure time as well as the concentration of the test material. In humans, AEs are less irritating to skin than in animals. Neat applications of a range AEs in a 4hour human patch test did not warrant these chemicals to be classified as skin irritants under EU legislation, while the same AEs would have been classified for skin irritation on the basis of animal data.

Alcohol ethoxylates range from mildly to severely irritating to rabbit eyes. Rinsing the eyes directly after exposure with water for 20 to 30 seconds greatly reduced the severity of the effects such that these products produced only mildly irritating effects. The degree of irritation is concentration-dependent as dilutions in water cause proportionally lower irritation. Generally, concentration of 0.1% were non-irritating, and concentrations of 1 to 10% ranged from slight to moderately irritating. No relationship could be established between the chemical structures of the tested AEs and their eye irritation responses.

Sensitization

Alcohol ethoxylates should not be considered as skin sensitizers. A substantial amount of skin sensitization studies in guinea pigs following either the Magnusson-Kligman maximization or the Buehler testing protocol are available to evaluate the skin sensitization potential of AEs. Although a mild skin sensitization reaction was observed in a study following the Magnusson-Kligman protocol, the weight of evidence clearly supports the assessment that AEs should not be considered as skin sensitizers. This is further supported by clinical and market data that demonstrate the absence skin sensitization responses to AEs when tested under the conditions of the HRIPT or when used in AE containing consumer products.

Repeated Dose Toxicity

C10AE5 was fed to rats at doses of 0, 125, 250 or 500 mg/kg for 90 days. There were no

treatment-related clinical signs, body weight gain, food consumption or feed efficiency. There was a slight increase in absolute liver weights as well as a trend toward a dose-dependent increase in the liver weight/body weight ratio, with a statistically significant increase in the high dose group. However, the histological evaluation did not reveal any indication of hepatotoxicity and therefore the increase in liver weights was not interpreted to be a toxicological effect. It can be considered to be an adaptive response as a result of extensive metabolism of the test compound by the liver. There were no other gross or histopathological changes that were considered treatment-related. The NOAEL for this study can be considered to be 500 mg/kg/day.

Rats were given in their diet 0, 125, 250, 500, 1,000 or 3,000 ppm C9-11AE6 for 90 days. There were no signs of toxicity at any dose level. The NOAEL is 3,000 ppm (approximately 150 mg/kg/day).

Rats were given in their diet 0, 0.04, 0.2 or 1.0% C9-11AE8 for 90 days. Lower body weight gain and decreased food consumption were noted in the 1% males and females and in the 0.2% females from week 1 through the end of the study. Further statistical analyses revealed a significant decrease in the mean body weight gain noted in the 1% females and the decreases in mean food consumption noted in the 1% males and females. The differences noted in the 0.2% females were not statistically significant. The investigators considered these observations to be the result of poor palatability of the test substance. There were no other treatment-related effects. The NOAEL for this study is 1.0% (about 400 mg/kg/day).

Rats were fed C12-15AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% or 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the $\geq$0.25% groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the $\geq$0.25% groups. There were not treatment-related changes in hematology, urinary and clinical chemistry parameters. Liver cell enlargement was seen in the $\geq$0.125% groups, suggesting increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (102 mg/kg/day).

Rats were fed C12-14AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% or 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the $\geq$0.25% groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the $\geq$0.25% groups. There were no treatment-related changes in hematology, urinary and clinical chemistry parameters. Liver cell enlargement was seen in the $\geq$0.125%, suggesting increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (110 mg/kg/day).

Wistar rats were fed C14-15AE7 in the diet at concentrations of 0, 300, 1,000, 3,000, or 10,000 ppm for 90 days. All animals survived until their scheduled necropsy date.

Significant treatment-related effects on body weight (*i.e.*, reduced mean body weights in males at 10,000 ppm and in females at 3,000 ppm), food intake (*i.e.*, reduced intake in both sexes at 10,000 ppm and at 3,000 ppm for females), organ weights (*i.e.*, increased relative liver weight in both sexes at 3,000 and 10,000 ppm and in females also at 1,000 ppm; increased spleen weight in males at 10,000 ppm; clinical chemistry (*i.e.*, confined to 10,000 ppm dose groups; significantly higher urea, chloride and potassium levels in males; significantly higher urea, chloride and cholesterol levels in females) and hematology (*i.e.*, in both sexes at 10,000 ppm and in males also at 3,000 ppm increased total leukocytes and lymphocytes; females at 10,000 ppm showed depression in numbers of neutrophils, mean cell volume and mean cell hemoglobin) were identified in one or both sexes fed with dietary concentrations of 3,000 and 10,000 ppm. There were no compound-related histopathological effects at any dose level. Minor, but statistically significant changes in liver weight, kidney weights and plasma urea concentration were recorded in female rats in the 1,000 ppm group were not of toxicological significance. The NOAEL for this study is 1,000 ppm (50 mg/kg/day).

Rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1%, 0.5% or 1% for 90 days. There were no treatment-related changes in body weight, food intake, and organ weights including those of the reproductive system, clinical chemistry and hematology at any treatment level. The NOAEL is 1% in the diet, which corresponded to 700 and 785 mg/kg-day for males and females, respectively.

Rats were fed C12-13AE6.5 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Rats were fed C14-15AE7 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Charles River rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was a dose-related decrease in body weights in the 0.5 and 1% females and in the 1% males, the likely cause being poor palatability of the diet. At study termination, elevated organ-to-body weight ratios were noted for the liver, kidney, heart and thyroid/parathyroid glands in the 1% dietary group. The only significant histopathological finding prevalent in all dose groups was a dose-related increase in incidence of focal myocarditis at 12 months but not at study termination at 2 years. No other treatment-related histopathology was noted. The NOAEL was established at the

0.5% dietary level, which corresponds to about 162 and 190 mg/kg-day for males and females, respectively.

Genotoxicity

In all available *in vitro* and *in vivo* genotoxicity assays, there was no indication of genetic toxicity of broad range of structurally different alcohol ethoxylates.

Carcinogenicity

Alcohol ethoxylates as a class are not carcinogenic by the oral route based of available oral long term toxicity/carcinogenicity studies on AEs.

Charles River rats were given in their diet 0, 0.1, 0.5 or 1% C14-15AE7 for two years. There was no treatment-related changes in general behavior and appearance. The survival rate of the test animals was comparable if not better than the controls. Body weights of 0.5% females and 1% males and females had significantly lower weight gains than the control. There were no treatment-related effects on organ weights and tumor incidence.

Sprague-Dawley rats were fed C14-15AE7 at 0.1, 0.5 or 1% in the diet for two years. A treatment-related body weight depression was observed in females at the two highest treatment levels and in males at the 1% dose level, probably due to the poor palatability of the diet. There was no evidence for any carcinogenic activity.

Sprague-Dawley rats were fed C12-13AE6.5 in the diet at doses up to 1% (500 mg/kg-day). Reduced food consumption was noted at the higher dose levels (*i.e.*, 0.5 and 1% for females and 1% for males), resulting in a lower body weight gain compared to the control group. No treatment-related histopathology was found and no increase in tumor incidence was observed.

Reproductive Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg-day).
No treatment related effects in the parents or pups on general behavior, appearance or survival were observed. Fertility of treated groups was comparable with the controls. The only observation was related to a reduced weight gain of parental rats and pups relative to the control at the 0.5% dose level. The NOAEL for reproduction was therefore set at the highest dose level which was 0.5% dietary level (250 mg/kg-day).

In a two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg-day). Three of the groups received the compound continuously during the study. In the

other three groups the females received the compound only during the 6th through the 15th day of gestation and the males were untreated. No treatment-related changes in behavior or appearance were observed in the parental rats or pups throughout the study. Female rats from the 0.5% continuous treatment group gained slightly less body weight compared to control females. No other consistent differences in body weight were observed. Food consumption was similar for control and treated rats. No compound related differences were seen between control and treated rats with respect to fertility, gestation or viability indices. The average 21-day body weights for pups at the 0.5% continuous treatment group were significantly lower as compared to the average pup body weights in the controls. No other compound-related changes in body weight were observed. None of the deaths of parental rats during the study was considered to be compound-related. Examination of organ weight values revealed that compound-related effects were limited to increased group mean relative liver weights of male and female F1 from the 0.5% continuous feeding group at the 91-day sacrifice, and increases in group mean relative liver weights of males from the 0.5% continuous feeding group of the F2 generation at the 60-day and caesarean section sacrifices. No compound-related histopathological lesions were observed in any of the tissues examined from rats for the F_0 and F_1 generations. The NOAEL for reproductive toxicity is at least 0.5% in the diet (250 mg/kg/day).

Developmental Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg-day). General behavior, appearance and survival were not affected by treatment. At the 0.5% dose level, adults and pups gained less weight than the control rats. In the 0.5% dose group, there was a statistical increase in embryo lethality and soft tissue anomalies and at the 0.1% there was a statistical decrease in mean fetal liver weight. Neither of these effects was considered to be treatment-related by the authors as they showed no dose response characteristics. The NOAEL for maternal toxicity is 50 mg/kg/day. The NOAEL for developmental and teratogenicity is 0.1% (50 mg/kg/day).

Pregnant rabbits were given by oral gavage 0, 50, 100 or 200 mg/kg C12AE6 from GD 2 to16. Nine control rabbits and 31 treated rabbits died during the study. Surviving rabbits at the 200 mg/kg dose level generally showed slight losses of body weight. At 100 and 200 mg/kg, ataxia and a slight decrease in body weight was observed in the pregnant animals. In seven treated and two control rabbits early deliveries were recorded. There were no treatment-related effects on corpora lutea, implantations, number of live fetuses and spontaneous abortions. The NOAEL for maternal toxicity is 50 mg/kg/day; the NOAEL for developmental toxicity is 200 mg/kg/day.

In two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg/day). On the 13th day of the gestation period a representative number of female rats from each treatment group of the FC generation (*i.e.*, pups from the 3rd mating of the F_0 and F_1 parental generation) were sacrificed. Laparotomies were performed and the uterus was

examined for uterine abnormalities, normal implantation and resorption sites. Remaining females were sacrificed on the 21st day of gestation. Various maternal and fetal parameters showed occasional values that were significantly different from the corresponding controls. However these were not considered related to the material tested as none occurred at the high feeding level and no dose response for these parameters was apparent. With respect to body weight gains, parental female rats and pups of the high dose group did not gain as much body weight as the control rats. Examination of organ weight values reveal compound related effects were limited to increased group mean liver weighs of male and female P_1 generation from the 0.5% continuous feeding group at the 91 day sacrifice and increase in group mean relative liver weights of males of the 0.5% continuous feeding group of the P_2 generation at the 60 day section sacrifices. The NOAEL for maternal and developmental toxicity was established at the 0.1% in the diet (50 mg/kg/day).

Key Study/Critical Effect for Screening Criteria

AEs of different structures with regard to the length of the alkyl chain and the degree of ethoxylation have been evaluated in a number of 90-day and two-year oral toxicity studies. The lowest NOAEL of AEs for systemic toxicity was established at 50 mg/kg-day in two chronic (two-year) dietary studies on C12-13AE6.5 and C14-15AE7. Effects observed at the LOAEL were related to significantly elevated organ-to-body weight ratios for liver, kidney and heart, although there were no adverse histopathological changes.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 50/100 = 0.5 mg/kg/day

Drinking water guidance value = 2 ppm

Toxicity Profile

Alcohols, C10-C16, Ethoxylated Propoxylated
(CAS No. 69227-22-1)

No toxicity information could located on alcohols, C10-C16, ethoxylated propoxylated (CAS No. 69227-22-1). Toxicity information is available on alcohol ethoxylates. Alcohols, C10-C16, ethoxylated propoxylated is produced by the use of propylene oxide (PO) in addition to ethylene oxide (EO) during the alkoxylation of the alcohol(s). the PO is either incorporated randomly by alkoxylation within the epoxide mixture, or in a block by sequencing the addition of EO and PO to the reactor. Because of the similarity in structures, the toxicity data on the alcohol ethoxylates were used to read-across to alcohols, C10-16, ethoxylated propoxylated.

Alcohol ethoxylates are a class of non-ionic surfactants. The AEs have the basic structure $C_{x-y}AE_n$. The subscript (x-y) following the 'C' indicates the range of carbon chain units. AEs with carbon unit range between C8 to C18 are most commonly used in household detergent products. The hydrocarbon chain can be either linear or branched. AEs also contain an ethylene oxide (E) chain attached to the alcohol. The degree of ethylene oxide polymerization is indicated by the subscript (n) which indicates the average number of ethylene oxide units. In household products the average ethylene oxide chain length commonly ranges between 3 and 12 units.

Acute Toxicity

The acute oral LD_{50} of C9-11AE2.5 in rats was calculated to be >4,000 mg/kg and <10,000 mg/kg. The acute oral LD_{50} of C7-9AE6 in rats was determined to be <2,000 mg/kg. The acute oral LD_{50} of C9-11AE8 in fasted rats was found to be 1,200 mg/kg. The oral LD_{50} in rats for C12-13AE6.5 is 2,100 mg/kg. The oral LD_{50} in rats for C12-15AE7 is 1,700 mg/kg. For C14-15AE11, the acute oral LD_{50} values were reported to be 720 mg/kg (neat) and 1,800 mg/kg (given as 50% (m/v) solution in corn oil). The oral LD_{50} in rats for C12-15AE11 is >2,00 mg/kg for males and between 1,000 and 2,000 mg/kg for females. The oral LD_{50} in rats for C14-15AE13 is 1,100 and 1,000 mg/kg in two separate studies.

The dermal LD_{50} of C7-9AE6 was >2,000 mg/kg. The dermal LD_{50} values for AEs with an alkyl chain length of 9 – 11 carbon atoms in three different rat studies were determined to be >2,000 mg/kg and >4,000 mg/kg. An acute dermal LD_{50} value of >2,000 mg/kg was determined for C12-14AE3 and C12-14AE6 in two separate studies. The acute dermal LD_{50} of C12-15AE7 was determined to be >2,000 mg/kg.

The acute rat 4-hour LC_{50} of C9-11AE5 generated as a mist was determined to be >0.22 mg/L. Talmage (1994) reported that alcohol ethoxylates were not acutely toxic to rats at concentrations less than or equal to their saturated vapor concentrations in air. Acute

toxic thresholds were reached only when animals were exposed to the undiluted test chemical in the form of a respirable mist or aerosol. Under these conditions, 1- or 4-hour inhalation LC_{50} values ranged from 1.5 to 20.7 mg/L. Some studies reported no mortalities (1-hour LC_{50} -study) occurred at concentrations as high as 52 mg/L.

Irritation

Alcohol ethoxylates with varying alkyl chain lengths and ethoxylation degree were found to be slightly to severely irritating to skin in rabbits and rats. The degree of irritation was dependent on the type of patches used (open application versus full occlusion), the exposure time as well as the concentration of the test material. In humans, AEs are less irritating to skin than in animals. Neat applications of a range AEs in a 4hour human patch test did not warrant these chemicals to be classified as skin irritants under EU legislation, while the same AEs would have been classified for skin irritation on the basis of animal data.

Alcohol ethoxylates range from mildly to severely irritating to rabbit eyes. Rinsing the eyes directly after exposure with water for 20 to 30 seconds greatly reduced the severity of the effects such that these products produced only mildly irritating effects. The degree of irritation is concentration-dependent as dilutions in water cause proportionally lower irritation. Generally, concentration of 0.1% were non-irritating, and concentrations of 1 to 10% ranged from slight to moderately irritating. No relationship could be established between the chemical structures of the tested AEs and their eye irritation responses.

Sensitization

Alcohol ethoxylates should not be considered as skin sensitizers. A substantial amount of skin sensitization studies in guinea pigs following either the Magnusson-Kligman maximization or the Buehler testing protocol are available to evaluate the skin sensitization potential of AEs. Although a mild skin sensitization reaction was observed in a study following the Magnusson-Kligman protocol, the weight of evidence clearly supports the assessment that AEs should not be considered as skin sensitizers. This is further supported by clinical and market data that demonstrate the absence skin sensitization responses to AEs when tested under the conditions of the HRIPT or when used in AE containing consumer products.

Repeated Dose Toxicity

C10AE5 was fed to rats at doses of 0, 125, 250 or 500 mg/kg for 90 days. There were no treatment-related clinical signs, body weight gain, food consumption or feed efficiency. There was a slight increase in absolute liver weights as well as a trend toward a dose-dependent increase in the liver weight/body weight ratio, with a statistically significant increase in the high dose group. However, the histological evaluation did not reveal any

indication of hepatotoxicity and therefore the increase in liver weights was not interpreted to be a toxicological effect. It can be considered to be an adaptive response as a result of extensive metabolism of the test compound by the liver. There were no other gross or histopathological changes that were considered treatment-related. The NOAEL for this study can be considered to be 500 mg/kg/day.

Rats were given in their diet 0, 125, 250, 500, 1,000 or 3,000 ppm C9-11AE6 for 90 days. There were no signs of toxicity at any dose level. The NOAEL is 3,000 ppm (approximately 150 mg/kg/day).

Rats were given in their diet 0, 0.04, 0.2 or 1.0% C9-11AE8 for 90 days. Lower body weight gain and decreased food consumption were noted in the 1% males and females and in the 0.2% females from week 1 through the end of the study. Further statistical analyses revealed a significant decrease in the mean body weight gain noted in the 1% females and the decreases in mean food consumption noted in the 1% males and females. The differences noted in the 0.2% females were not statistically significant. The investigators considered these observations to be the result of poor palatability of the test substance. There were no other treatment-related effects. The NOAEL for this study is 1.0% (about 400 mg/kg/day).

Rats were fed C12-15AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% or 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the $\geq$0.25% groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the $\geq$0.25% groups. There were not treatment-related changes in hematology, urinary and clinical chemistry parameters. Liver cell enlargement was seen in the $\geq$0.125% groups, suggesting increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (102 mg/kg/day).

Rats were fed C12-14AE7 in the diet at concentrations of 0%, 0.0313%, 0.0625%, 0.125%, 0.25%, 0.5% or 1.0% for 90 days. Body weight gain was significantly reduced in male and female rats in the $\geq$0.25% groups, and was associated with marked decreases in food and water consumption. Relative liver weights were significantly increased in the 0.5% and 1% male rats fed and in female rats in the $\geq$0.25% groups. There were no treatment-related changes in hematology, urinary and clinical chemistry parameters. Liver cell enlargement was seen in the $\geq$0.125%, suggesting increased liver metabolism on the basis of increased alkaline phosphatase activity at the higher dose levels. The NOAEL was established at 0.0625% (110 mg/kg/day).

Wistar rats were fed C14-15AE7 in the diet at concentrations of 0, 300, 1,000, 3,000, or 10,000 ppm for 90 days. All animals survived until their scheduled necropsy date. Significant treatment-related effects on body weight (*i.e.*, reduced mean body weights in males at 10,000 ppm and in females at 3,000 ppm), food intake (*i.e.*, reduced intake in both sexes at 10,000 ppm and at 3,000 ppm for females), organ weights (*i.e.*, increased relative liver weight in both sexes at 3,000 and 10,000 ppm and in females also at 1,000

ppm; increased spleen weight in males at 10,000 ppm; clinical chemistry (*i.e*., confined to 10,000 ppm dose groups; significantly higher urea, chloride and potassium levels in males; significantly higher urea, chloride and cholesterol levels in females) and hematology (*i.e*., in both sexes at 10,000 ppm and in males also at 3,000 ppm increased total leukocytes and lymphocytes; females at 10,000 ppm showed depression in numbers of neutrophils, mean cell volume and mean cell hemoglobin) were identified in one or both sexes fed with dietary concentrations of 3,000 and 10,000 ppm. There were no compound-related histopathological effects at any dose level. Minor, but statistically significant changes in liver weight, kidney weights and plasma urea concentration were recorded in female rats in the 1,000 ppm group were not of toxicological significance. The NOAEL for this study is 1,000 ppm (50 mg/kg/day).

Rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1%, 0.5% or 1% for 90 days. There were no treatment-related changes in body weight, food intake, and organ weights including those of the reproductive system, clinical chemistry and hematology at any treatment level. The NOAEL is 1% in the diet, which corresponded to 700 and 785 mg/kg-day for males and females, respectively.

Rats were fed C12-13AE6.5 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Rats were fed C14-15AE7 in their diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was reduced food consumption in males (1%) and females (0.5 and 1%) which resulted in lower body weight gain compared to controls. At study termination, organ to body weight ratios were increased in the 0.5 and 1% females (liver, kidney and brain), 1% females (heart), and 1% males (liver). A dose-related focal myocarditis was observed in males. The NOAEL was established at 0.1% dietary level based on the relative organ weight increases. This corresponds to 50 mg/kg/day.

Charles River rats were fed C14-15AE7 in the diet at concentrations of 0, 0.1, 0.5 or 1% for two years. There was a dose-related decrease in body weights in the 0.5 and 1% females and in the 1% males, the likely cause being poor palatability of the diet. At study termination, elevated organ-to-body weight ratios were noted for the liver, kidney, heart and thyroid/parathyroid glands in the 1% dietary group. The only significant histopathological finding prevalent in all dose groups was a dose-related increase in incidence of focal myocarditis at 12 months but not at study termination at 2 years. No other treatment-related histopathology was noted. The NOAEL was established at the 0.5% dietary level, which corresponds to about 162 and 190 mg/kg/day for males and females, respectively.

Genotoxicity

In all available *in vitro* and *in vivo* genotoxicity assays, there was no indication of genetic toxicity of broad range of structurally different alcohol ethoxylates.

Carcinogenicity

Alcohol ethoxylates as a class are not carcinogenic by the oral route based of available oral long term toxicity/carcinogenicity studies on AEs.

Charles River rats were given in their diet 0, 0.1, 0.5 or 1% C14-15AE7 for two years. There was no treatment-related changes in general behavior and appearance. The survival rate of the test animals was comparable if not better than the controls. Body weights of 0.5% females and 1% males and females had significantly lower weight gains than the control. There were no treatment-related effects on organ weights and tumor incidence.

Sprague-Dawley rats were fed C14-15AE7 at 0.1, 0.5 or 1% in the diet for two years. A treatment-related body weight depression was observed in females at the two highest treatment levels and in males at the 1% dose level, probably due to the poor palatability of the diet. There was no evidence for any carcinogenic activity.

Sprague-Dawley rats were fed C12-13AE6.5 in the diet at doses up to 1% (500 mg/kg/day). Reduced food consumption was noted at the higher dose levels (*i.e.*, 0.5 and 1% for females and 1% for males), resulting in a lower body weight gain compared to the control group. No treatment-related histopathology was found and no increase in tumor incidence was observed.

Reproductive Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg-day). No treatment related effects in the parents or pups on general behavior, appearance or survival were observed. Fertility of treated groups was comparable with the controls. The only observation was related to a reduced weight gain of parental rats and pups relative to the control at the 0.5% dose level. The NOAEL for reproduction was therefore set at the highest dose level which was 0.5% dietary level (250 mg/kg/day).

In a two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg/day). Three of the groups received the compound continuously during the study. In the other three groups the females received the compound only during the 6th through the 15th day of gestation and the males were untreated. No treatment-related changes in behavior or appearance were observed in the parental rats or pups throughout the study. Female rats from the 0.5% continuous treatment group gained slightly less body weight

compared to control females. No other consistent differences in body weight were observed. Food consumption was similar for control and treated rats. No compound related differences were seen between control and treated rats with respect to fertility, gestation or viability indices. The average 21-day body weights for pups at the 0.5% continuous treatment group were significantly lower as compared to the average pup body weights in the controls. No other compound-related changes in body weight were observed. None of the deaths of parental rats during the study was considered to be compound-related. Examination of organ weight values revealed that compound-related effects were limited to increased group mean relative liver weights of male and female F_1 from the 0.5% continuous feeding group at the 91-day sacrifice, and increases in group mean relative liver weights of males from the 0.5% continuous feeding group of the F_2 generation at the 60-day and caesarean section sacrifices. No compound-related histopathological lesions were observed in any of the tissues examined from rats for the F_0 and F_1 generations. The NOAEL for reproductive toxicity is at least 0.5% in the diet (250 mg/kg/day).

Developmental Toxicity

In a two-generation reproductive toxicity study, Charles River rats were fed C12AE6 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg/day). General behavior, appearance and survival were not affected by treatment. At the 0.5% dose level, adults and pups gained less weight than the control rats. In the 0.5% dose group, there was a statistical increase in embryo lethality and soft tissue anomalies and at the 0.1% there was a statistical decrease in mean fetal liver weight. Neither of these effects was considered to be treatment-related by the authors as they showed no dose response characteristics. The NOAEL for maternal toxicity is 50 mg/kg/day. The NOAEL for developmental and teratogenicity is 0.1% (50 mg/kg/day).

Pregnant rabbits were given by oral gavage 0, 50, 100 or 200 mg/kg C12AE6 from GD 2 to 16. Nine control rabbits and 31 treated rabbits died during the study. Surviving rabbits at the 200 mg/kg dose level generally showed slight losses of body weight. At 100 and 200 mg/kg, ataxia and a slight decrease in body weight was observed in the pregnant animals. In seven treated and two control rabbits early deliveries were recorded. There were no treatment-related effects on corpora lutea, implantations, number of live fetuses and spontaneous abortions. The NOAEL for maternal toxicity is 50 mg/kg/day; the NOAEL for developmental toxicity is 200 mg/kg/day.

In two-generation developmental and teratogenicity study, CD rats were fed C14-15AE7 in the diet at dose levels of 0, 0.05, 0.1 or 0.5% (about 0, 25, 50 or 250 mg/kg/day). On the 13th day of the gestation period a representative number of female rats from each treatment group of the FC generation (*i.e.*, pups from the 3rd mating of the F_0 and F_1 parental generation) were sacrificed. Laparotomies were performed and the uterus was examined for uterine abnormalities, normal implantation and resorption sites. Remaining females were sacrificed on the 21st day of gestation. Various maternal and fetal parameters showed occasional values that were significantly different from the corresponding controls. However these were not considered related to the material tested

as none occurred at the high feeding level and no dose response for these parameters was apparent. With respect to body weight gains, parental female rats and pups of the high dose group did not gain as much body weight as the control rats. Examination of organ weight values reveal compound related effects were limited to increased group mean liver weighs of male and female P_1 generation from the 0.5% continuous feeding group at the 91 day sacrifice and increase in group mean relative liver weights of males of the 0.5% continuous feeding group of the P_2 generation at the 60 day section sacrifices. The NOAEL for maternal and developmental toxicity was established at the 0.1% in the diet (50 mg/kg/day).

Key Study/Critical Effect for Screening Criteria

AEs of different structures with regard to the length of the alkyl chain and the degree of ethoxylation have been evaluated in a number of 90-day and two-year oral toxicity studies. The lowest NOAEL of AEs for systemic toxicity was established at 50 mg/kg/day in two chronic (two-year) dietary studies on C12-13AE6.5 and C14-15AE7. Effects observed at the LOAEL were related to significantly elevated organ-to-body weight ratios for liver, kidney and heart, although there were no adverse histopathological changes.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 50/100 = 0.5 mg/kg/day

Drinking water guidance value = 2 ppm

Toxicity Profile

Choline chloride
Cholinium chloride
(CAS No. 67-48-1)

Choline chloride, also known as cholinium chloride, is a quaternary amine salt. It dissociates in water into the corresponding positively charged quaternary hydroxyl alkylammonium ion and the negatively charged chloride ion.

Choline chloride has been reviewed in the OECD-SIDS program (OECD, 2004).

Acute Toxicity

The oral LD_{50} in rats was reported to be between 3,150 and 5,000 mg/kg (BASF AG, 1963a, 1969).

Irritation

Application of a 70% aqueous solution to the skin of rabbits for 20 hours under occlusive conditions resulted in only minor skin irritation (BASF AG, 1963b). Slight eye irritation was seen in the eyes of rabbits after instillation of a 70% aqueous solution of choline chloride; no effects were seen one day after exposure (BASF AG, 1963c).

Sensitization

No data are available in animals. In a Human Repeated Insult Patch Test, there was no evidence of dermal sensitization in two hundred subjects given 0.5% (w/v) aqueous solution of choline chloride during the induction phase and 0.2% (w/v) aqueous solution during the challenge phase (Colgate-Palmolive, 2003).

Repeated Dose Toxicity

A 72-week feeding study was conducted to investigate the impact of choline chloride on the liver tumor promoting activity of phenobarbital and DDT in diethylnitroamine-initiated Fischer 344 rats (Shivapurkar *et al.*, 1986). Animals received approximately 500 mg/kg-day choline chloride. Following the end of the exposure period, the animals were keep on the same untreated diet as the control group until study termination at week 103. Histopathology was limited to the liver and organs that developed gross abnormalities. There were no significant differences between treated and control animals on survival rates, body weights, and relative liver weights. Neither was there any

increased number of neoplastic liver nodules, hepatocellular carcinomas, lung tumors, leukemia nor other tumors between treated and control animals. The NOAEL for choline chloride in this study is 500 mg/kg/day.

In humans, oral administration of 10,000 mg/day choline chloride in a pilot study treating a small number of patients with Alzheimer's disease, resulted in a slight hypotensive effect (Boyd *et al.*, 1977). This dose was regarded as a LOAEL by the Standing Committee on the Scientific Evaluation of Dietary Reference Intake (2000).

Genotoxicity

Choline chloride was not mutagenic to bacteria in reverse mutation assays (Haworth *et al.*, 1984; JETOC, 1997; Litton Bionetics, 1977).

A small, but statistically significant, and dose-related increase in sister chromatid exchanges (SCEs) in Chinese Hamster Ovary (CHO) cells was reported at 50 and 500 μg/ml choline chloride in the absence of S9 only (Bloom *et al.*, 1982). No higher concentrations were examined. These results could not be confirmed in another study using CHO cells at concentrations of choline chloride up to 5,000 μg/ml. (Galloway *et al.*, 1985).

In a gene conversion assay with *Saccharomyces cerevisiae* strain D4, choline chloride was negative in the presence and absence of metabolic activation (Litton Bionetics, 1977).

No *in vivo* genotoxicity studies were available.

Carcinogenicity

No studies were located.

Reproductive Toxicity

No reliable studies have been conducted that address female fertility or reproductive toxicity by a relevant route of exposure.

Developmental Toxicity

Pregnant female mice were given in their feed 1,250 to 20,000 mg/kg choline chloride during gestational days 1 to 18 (BASF AG, 1966). Maternal body weight gain was reduced in all treated groups except for the 1,250 mg/kg group. Determination of maternal weight gain of dams with embryonic/fetal absorptions showed that there was no

almost net weight gain at ≥4,160 mg/kg and net weight loss in the 20,000 mg/kg group. All fetuses were resorbed in the 20,000 mg/kg group. Embryonic/fetal lethality of 35% and 69% were seen in the 4,160 and 10,800 mg/kg groups, respectively. No resorptions occurred in the 1,250 mg/kg group. Developmental toxicity was seen in all but the 1,250 mg/kg group. No statistically significant increases in malformations were observed in any dose group. The NOAELs for maternal and developmental toxicity is 1,250 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The Standing Committee on the Scientific Evaluation of Dietary Reference Intakes selected hypotension as the critical effect from the study by Boyd *et al.* (1977) when deriving a Tolerable Upper Intake Level. Boyd *et al.* (1977) reported a LOAEL of 10,000 mg/day choline chloride (7,500 mg/day choline). An uncertainty factor of 2 was chosen because of the limited data regarding hypotension and the inter-individual variation in response to cholinergic effects. Thus, the value for the Tolerable Upper Intake Value for repeated exposure of adults to choline is 3,500 mg/day choline.

The oral RfD for choline chloride is derived by using the LOAEL of 10,000 mg/day from the Boyd *et al.* (1977) study, which is divided by an uncertainty factor of 2, to obtain a value of 5,000 mg/day or 71 mg/kg/day for a 70 kg person.

Oral RfD = 71 mg/kg/day

Drinking water guideline value = 248 ppm

Toxicity Profile

Cocoamidopropyl betaine
(CAS No. 61789-40-0)

Cocoamidopropyl betaine has been reviewed in the OECD-SIDS program (OECD, 2006).

Acute Toxicity

The acute toxicity of cocoamidopropyl betaine (30-35.5% aqueous solution) in rats is low. The oral LD_{50} is $\geq$4,900 mg/kg, and the dermal LD_{50} is >2,000 mg/kg.

Irritation

A 30% aqueous solution of cocoamidopropyl betaine was only very slightly irritating to the skin of rabbits. In human studies, up to 3% solutions were weakly irritating. A 5-10% solution of cocamidopropyl betaine produced mild to moderate irritation to the eyes of rabbits; solutions containing 15% were irritating to highly irritating; and a 30% aqueous solution was irritating with irreversible damage.

Sensitization

The sensitizing potential of cocoamidopropyl betaine in humans is low. Commercial cocoamidopropyl betaine may, however, contain impurities identified as sensitizers (amidoamine and/or 3-dimethylaminopropylamine) which may explain positive results in human patch tests. There is no evidence for a photosensitizing potential.

Repeated Dose Toxicity

Rats were given a 30% aqueous solution of cocoamidopropyl betaine by oral gavage at doses of 0, 250, 500 or 1,000 mg/kg/day (corresponding to about 0, 75, 150, and 300 mg active substance/kg/day, respectively) 5 days/week for 28 days (Henkel KgA, 1991). The only treatment-related findings were forestomach lesions at the highest dose level, probably as a result of the irritant effect of the test substance. The NOAEL for this study is 500 mg/kg/day (150 mg cocoamidopropyl betaine/kg/day).

Rats were given a 30% aqueous solution of cocoamidopropyl betaine by oral gavage at doses of 0, 250, 500 or 1,000 mg/kg/day (corresponding to about 0, 75, 150, and 300 mg active substance/kg/day, respectively) five days/week for 90 days (Th. Goldschmidt AG, 1991). The only treatment-related findings were forestomach lesions at the 500 and 1,000 mg/kg dose levels , probably as a result of the irritant effect of the test substance. The NOAEL for this study is 250 mg/kg day (75 mg cocoamidopropyl betaine/kg/day).

Genotoxicity

There is no evidence for a genotoxic potential of cocoamidopropyl betaine. A 30% aqueous solution of cocoamidopropyl betaine was not genotoxic i*n vitro* in either a bacteria mutation test or in a mouse lymphoma test. A limited intraperitoneal mouse micronucleus test with 27 % active cocamidopropyl betaine was negative.

Carcinogenicity

No valid carcinogenicity studies have been conducted.

Reproductive Toxicity

No reproductive toxicity studies have been conducted on cocoamidopropyl betaine. However, there was no evidence of an adverse effect on the reproductive organs in rats given oral doses of up to 1,000 mg/kg/day of a 30% aqueous solution of cocoamidopropyl betaine (300 mg active substance/kg/day) for 90 days (Th. Goldschmidt AG, 1991).

Developmental Toxicity

A 28.9% aqueous solution of cocoamidopropyl betaine was tested in a rat developmental toxicity at doses of 330, 990, and 3,300 mg/kg/day (corresponding to 95, 286, and 950 mg/kg/day, respectively) (CESIO, 2004). There were dose-related maternal toxic effects (reduced body weights and stomach ulcers) at 990 mg/kg/day and above. Embryotoxic effects (increased numbers of resorptions, decreased number of viable fetuses, decreased fetal body weight) were found only at the maternal toxic dose level of 3,300 mg/kg/day. The NOAEL for maternal toxicity was 330 mg/kg/day (corresponding to 95 mg active substance/kg-day) and the NOAEL for developmental toxicity was 990 mg/kg/day (corresponding to 286 mg active substance/kg/day).

Key Study/Critical Effect for Screening Criteria

The key study is a 90-day rat oral gavage study in which forestomach lesions were seen at dose levels of 500 and 1,000 mg/kg of a 30% aqueous solution of cocoamidopropyl betaine. The NOAEL for this study is 250 mg/kg/day (75 mg active substance/kg/ay).

$NOAEL_{adjusted}$ = 75 * 5/7 = 53.6 mg/kg/day

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 0.05 mg/kg/day

Drinking water guideline: 0.19 ppm

Toxicity Profile

Coffee Beans (Ground and Roasted)

The composition of a medium-roasted coffee (Clarke, 1987; IARC, 1991) is shown in the table below:

Components	Typical avg content (dry basis, %)		% extractable with water, 100ºC[a]
	Arabica	Robusta	
Alkaloids (caffeine)	1.3	2.4	75 - 100
Trigonelline (including roasted by-products)	1.0	0.7	85 - 100
Minerals (as oxide ash)	4.5	4.7	90
Acids			
Residual chlorogenic	2.5	3.8	100
Aquinic	0.8	1.0	100
Aliphatic	1.6	1.6	100
Sugars			
Sucrose	0.0	0.0	-
Reducing	0.3	0.3	100
Polysaccharides (unchanged from green)	33	37	10
Lignin	2.0	2.0	0
Pectins	3.0	3.0	-
Proteinaceous compounds			
Protein	10	10	15 – 20
Free amino acids	0.0	0.0	-
Lipids (coffee oil)	17	11	1
Caramelized or condensation products (*e.g.*, melanoidins) by difference	23	22.5	20-25
Volatile substances other than acids	0.1	0.1	40-80

[a]Maier (1981), for normal household brewing

The focus of this toxicity profile is on caffeine (CAS No. 58-08-2), which is water-soluble alkaloid. Caffeine has well known central nervous system (CNS) stimulatory properties, and the health benefits as well as the potential health concerns of caffeine have been well studied. The chemical names for caffeine are 1,3,7-trimethyl-2,6-dioxopurine; 1,3,7-trimethylxanthine; 2,7-dihydro-1,3,7-trimethyl-1H-purine-2,6-dione; and 7-methyltheophylline.

Caffeine has been widely consumed by most segments of the population worldwide. The U.S. FDA estimates that the average amount of caffeine consumed by the U.S. population between 2003 and 2008 was approximately 300 mg/person/day (FDA, 2012).

Caffeine is probably one of the most studied natural dietary ingredient. In 2004, the Institute of Medicine (IOM) (2004) prepared an extensive review on caffeine, discussing several issues pertaining to safety. Health Canada also released a review of the many studies dealing with caffeine and its health effects (Nawrot *et al.*, 2003).

Pharmacokinetics

Caffeine is rapidly and completely adsorbed in humans, with approximately 99% absorbed within 45 minutes of consumption (Carillo and Benitez, 2000). Plasma caffeine levels may be influenced by the diet or route of exposure, but peak plasma levels occur approximately 15 to 120 minutes after consumption (Mandel, 2002; Beach *et al.*, 1984; Bonati *et al.*, 1984; Collomp *et al.*, 1991). Caffeine is water soluble and is rapidly distributed throughout the body, detected in all bodily fluids, including saliva, breast milk, urine and semen (Beach *et al.*, 1984). Caffeine elimination follows first-order kinetics (Newton *et al.*, 1981), with the plasma half-life of caffeine at approximately 3 to 6 hours in healthy adults and does not accumulate in body fat or other tissues (Kaplan *et al.*, 1997; Nawrot *et al.*, 2003). Caffeine is rapidly metabolized and excreted (1-3 mg/kg/minute) in the urine (Kaplan *et al.*, 1997), and varies between species, with a slightly different metabolic route noted in rats (Nawrot *et al.*, 2003).

Acute toxicity

The LD_{50} of caffeine in rodents ranges from 185 to 400 mg/kg, depending on the species and strain (OECD, 2002a,b). In humans, the fatal acute oral dose is estimated at 10 and 14 g (approximately 160 to 230 mg/kg for a 60 kg person) (Hodgman, 1998). The serum caffeine concentration is the most reliable indicator of potential caffeine toxicity, with a serum caffeine concentration >100 μg/ml considered lethal in humans (Mrvos *et al.*, 1989). Human caffeine consumption at up to 10 g has caused convulsions and vomiting, with recovery in six hours (Dreisbach, 1974). An acute dose of one gram caffeine can cause adverse effects, progressing from restlessness, nervousness, and irritability to delirium, emesis, neuromuscular tremors and convulsions (IOM, 2004). However, caffeine consumption through the day at up to 900 mg has been reported without adverse effects (Nawrot *et al.*, 2003).

Repeated Dose Toxicity

Administration of high levels of caffeine in chronic rodent studies showed decreased weight gain, but in most studies caffeine administration in the diet or in the drinking water did not affect mortality rates of mice and rats, with the exception of two studies that reported a significant reduction in the average life span of rats consuming caffeine (IARC, 1991). Administration of caffeine in chronic toxicity and carcinogenicity studies showed no carcinogenic effects (IARC, 1991). The potential for caffeine to induce genotoxicity has been evaluated in both *in vitro* an *in vivo* studies, with *in vitro* studies indicating both genotoxic and non-genotoxic results; *in vivo* studies have shown that, overall, caffeine is not genotoxic (IARC, 1991; OECD, 2002a,b).

Cardiovascular Effects

Caffeine is a stimulant, and has been studied for its physiological and behavioral effects. Caffeine increases heart rate and blood pressure, increases diuresis, increases locomotion and alertness, and decreases sleepiness. Clinical studies indicate that doses <450 mg do

not increase the risk or severity of cardiac arrhythmia, while acute doses of 150 mg caffeine may decrease heart rate (James, 1991; Green *et al.*, 1996; Myer, 1998). Studies evaluating effects of caffeine on cardiovascular health or serum cholesterol levels have not provided a consistent adverse effect with caffeine consumption (Nawrot *et al.*, 2003).

Reproductive and Developmental Toxicity

Studies that evaluated the potential teratogenicity of caffeine have been discussed in a review (Christian and Brent, 2001). In animal studies, caffeine administration to pregnant animals has been found to induce teratogenicity and toxic effects on the development of the fetuses only at doses that also caused toxic effects in the dams (Christian and Brent, 2001). Christian and Brent (2001) concluded that studies reporting positive teratogenic effects were administering large doses of caffeine that were far greater than human consumption and were providing the caffeine via gavage, which results in much higher peak serum caffeine levels and therefore overstates toxicity potential. Neither rodents or humans could attain such peak exposures by consuming solutions of caffeine over several hours, the usual mode of human caffeine consumption.

There have been questions raised on whether high intake of coffee or caffeine may increase the risk of miscarriage. Caffeine crosses the placenta and increases maternal catecholamine levels (Goldstein and Warren, 1962). The American College of Obstetricians and Gynecologists (2010) have concluded the following: "Moderate caffeine consumption (less than 200 mg per day) does not appear to be a major contributing factor in miscarriage or preterm birth. The relationship of caffeine to growth restriction remains undetermined. A final conclusion cannot be made at this time as to whether there is a correlation between high caffeine intake and miscarriage."

Conclusions

Based on animal and clinical studies, the long history of caffeine use, moderate daily consumption of caffeine does not appear to cause an irreversible adverse effect on human health.

Drinking Water Guidance Value

Nawrot *et al.* (2003) concluded in their review of the effects of caffeine on human health that "for the healthy adult population, moderate daily caffeine intake at a dose level up to 400 mg/day (equivalent to 6 mg/kg body weight/day in a 65-kg person) is not associated with adverse effects such as general toxicity, cardiovascular effects, effects on bone status and calcium balance (with consumption of adequate calcium), changes in adult behavior, increased incidence of cancer and effects on male fertility." It was indicated that habitual daily use of caffeine at greater than 500-600 mg/day (8.3 - 10 mg/kg) (4-7 cups of coffee or 7-9 cups of tea) could be considered a health risk. For women, caffeine intake greater than 400 mg/day (6.7 mg/kg) "may increase the risk of detrusor instability (unstable bladder) development in women" (Nawrot *et al.*, 2003).

More recently, the American College of Obstetricians and Gynecologists (2010) have concluded that moderate caffeine consumption (<200 mg/day) does not appear to be a major contributing factor in miscarriage or preterm birth.

Thus, the acceptable daily intake of caffeine will be set at 200 mg/person/day for the derivation of a drinking water guidance value. Assuming that humans consume 2 liters of water a day, the drinking water guidance value for caffeine is determined to be 100 mg/L.

Toxicity Profile

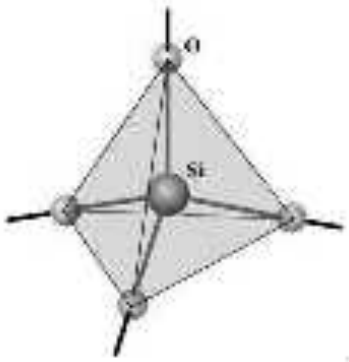
Crystalline Silica, Cristobalite
(CAS No 14464-46-1)

Crystalline Silica, Quartz
(CAS No. 14808-60-7)

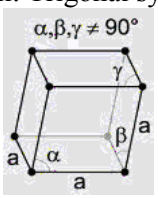
Silica is an off-white granule that occurs naturally in various crystalline and amorphous or other non-crystalline forms. Crystalline silica is characterized by silicon dioxide (SiO_2) molecules oriented in fixed, periodic patterns to form stable crystals. The primary crystalline form of silica is quartz. Other crystalline forms of silica include cristobalite, tripoli and tridymite. Particle size is a key determinate of silica toxicity, since toxicity is restricted to particles that are small enough to be deposited into the target regions of the respiratory tract.

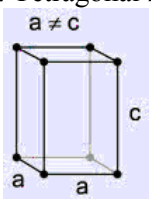
Oral Exposure

No oral studies were located; however, crystalline silica is not expected to exhibit toxicity by the oral route. Although absorption studies were not found for crystalline silica, kinetic studies on amorphous silica show no absorption from the gastrointestinal tract.



Dermal Exposure





No dermal studies were located; however, crystalline silica is not expected to exhibit toxicity by the dermal route.

Inhalation Exposure

See attached OECD-SIDS Initial Targeted Assessment Profile on Quartz and Cristobalite, SIAM 32, 19-21 April 2011.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

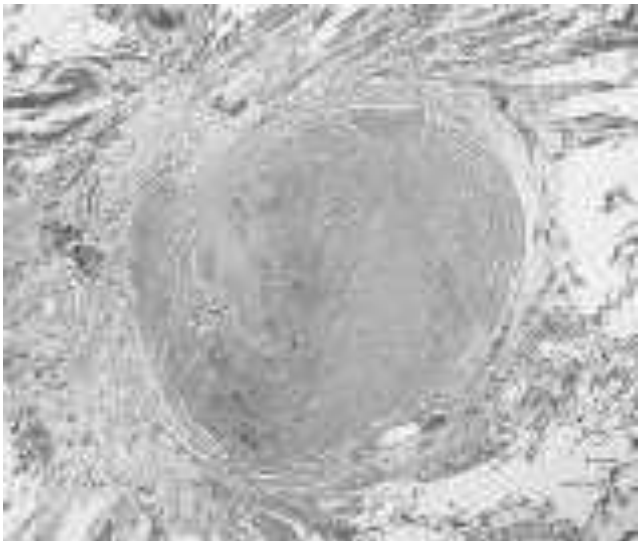


Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

conducted with crystalline silica: quartz, except where indicated).

Assay	Animal data		Human data		Positives/Total	
	In vitro	In vivo	In vitro	In vivo[d]	In vitro	In vivo
Rec Assay	0/1				0/1	
DNA strand break	1/1	2/2	5/5[b]	1/1	6/6	3/3
Sister chromatid exchange	0/1		0/1[c]	1/1	0/2	1/1
Micronucleus	2/3	0/1	2/2[b]	1/1	4/5	1/2
Chromosome aberration	0/1			1/1	0/1	1/1
Aneuploidy/polyploidy	0/3				0/3	
Cell transformation	4/4				4/4	
Hprt mutation	1/2	2/2[a]	1/1[b]		2/3	2/2
Oxidative DNA damage		4/5	2/2		2/2	4/5
DNA binding		1/1				1/1
p53 activation		0/1				0/1

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

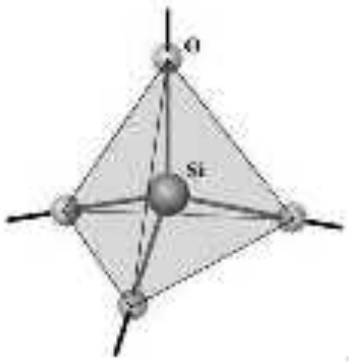
bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

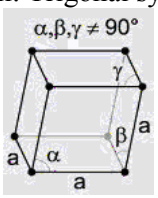
Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

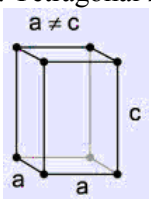
Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.



OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.





RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

INITIAL TARGETED ASSESSMENT PROFILE (Human Health)

CAS No.	Quartz: CAS RN 14808-60-7 Cristobalite: CAS RN 14464-46-1
Chemical Name	Quartz and Cristobalite
Structural Formula	Molecular Formula: SiO_2 

Unit Cell: Trigonal symmetry	Unit Cell: Tetragonal symmetry
	
Quartz: CAS RN 14808-60-7	Cristobalite: CAS RN 14464-46-1

SUMMARY CONCLUSIONS OF THE TARGETED ASSESSMENT

NOTE: The present assessment is targeted to address the following human health endpoints: repeated dose toxicity and carcinogenicity via the inhalation route of exposure, and genotoxicity. It cannot be considered as a full SIDS Initial Assessment. Summary information on exposure is also reported here. Other endpoints for human health and the environment included in the Canadian screening assessment but have not been presented to OECD member countries, and thus are not included in this profile.

The final screening assessment will be published under the responsibility of the Government of Canada.

Rationale for Targeting the Assessment

The Government of Canada "categorized" or prioritized all 23,000 chemical substances on its Domestic Substances List (DSL) from 1999 to September 2006, as required by its *Canadian Environmental Protection Act, 1999* (CEPA 1999). Additional details may be found at http://www.chemicalsubstanceschimiques.gc.ca/about-apropos/categor/index-eng.php. Using information from Canadian industry, academic research and other countries, Government of Canada scientists applied a set of rigorous tools to the 23,000 chemical substances on the DSL. They were categorized to identify those that were: **inherently toxic** to humans or to the environment and that might be **persistent** and/or **bioaccumulative**; and substances to which people might have **greatest potential for exposure**. During this priority-setting exercise, distinct approaches were taken for identifying substances of likely concern for human health and the environment, and subsequent assessment activities may have focused on either human health or ecological endpoints. Through categorization, the Government of Canada has identified approximately 4,000 of the 23,000

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

chemical substances on the DSL as priorities for further assessment, research and/or measures to control their use or release. Quartz and cristobalite were identified at that time, applying the categorization criteria, as high priorities for human health risk because they were considered to pose greatest potential for exposure and their respirable forms are classified by the International Agency for Research on Cancer as carcinogenic to humans (quartz and cristobalite) and by the National Toxicology Program as known human carcinogens (crystalline silica). These substances did not meet the ecological categorization criteria for bioaccumulation potential or inherent toxicity to aquatic organisms.

Under the Canadian legislation a determination of whether one or more of the criteria of the CANADIAN ENVIRONMENTAL PROTECTION ACT (CEPA) 1999, section 64 are met is based upon an assessment of potential risks to the environment and/or to human health associated with exposures in the general environment. For humans, this includes, but is not limited to, exposures from ambient and indoor air, drinking water, foodstuffs, and the use of consumer products. A conclusion under CEPA 1999 on the substances in the Chemicals Management Plan (CMP) Challenge is not relevant to, nor does it preclude, an assessment against the hazard criteria specified in the Controlled Products Regulations, which is part of the regulatory framework for the Workplace Hazardous Materials Information System [WHMIS] for products intended for workplace use.

Physical-chemical properties

The silicon dioxide group represents a polymorphic category containing a large number of forms identical in composition but with different atomic arrangements which afford different chemical properties. There are two sub-categories within this group: crystalline silica, to which the present substances quartz and cristobalite belong, and non-crystalline or amorphous silica. The key distinction between these sub-categories is that in crystalline substances, the building blocks are arranged in regular, repeating 3-dimensional pattern having long range order, whereas amorphous materials do not display long range order. In all forms of silica, (crystalline and non-crystalline), the silicon atom is tetrahedral and bound to four neighbouring oxygen atoms.

Quartz and cristobalite are solid at room temperature, existing normally as colourless or white crystals. The melting points for quartz and cristobalite are 1400-2000 ^{o}C and 1713-1728 ^{o}C, respectively and for both compounds, the boiling point is 2230^{o}C. Even though no experimental data were available, their vapour pressure and Henry's Law constant are likely negligible. Log K_{ow} (octanol-water partition coefficient) and log K_{oc} (organic carbon-water partition coefficient) are not applicable to these substances. The densities range from 2500-2700 kg/m^3 for quartz and 2300-2380 kg/m^3 for cristobalite.

The very similar physico-chemical properties of quartz and cristobalite reflect their closely related crystal forms. The solubility of crystalline silicates decreases as a function of silica tetrahedral packing density and long-range crystal order. For example, cristobalite has a more open framework structure than quartz and its density is lower, therefore, its solubility is higher. The water solubility of these minerals is also function of temperature, pH, particle size, and the presence of a disrupted surface layer. This may explain the variability of solubility values reported by many authors. The most probable solubility value for quartz is approximately 3.8 mg Si/L, or 6.4 mg/L expressed as the SiO_2 species, while the solubility of cristobalite is approximately 8.7 mg Si/L, or 18 mg SiO_2/L. The kinetics of dissolution of these substances is slow due to the high activation energy required to hydrolyse the Si-O-Si bond.

Human Health Targeted Endpoints

The majority of the studies described here have been reviewed by the International Agency for Research on Cancer (IARC 1997). However, additional data relevant to the screening assessment were identified up to August 2010.

Repeated dose toxicity/non-neoplastic effects (development of silicosis).

Studies on animals

Significant short-term and subchronic studies have demonstrated adverse effects in the lungs, while one of the 6 studies showed effects on the spleen in mice. Rats were exposed to 0, 10 or 100 mg/m^3 of cristobalite via inhalation for 6 hours/day during 3 days. Animals were observed 3 months after exposure. Elevated levels of granulocytes and elevated markers of cytotoxicity from the lung lavage fluid were noted in all exposed groups. Another study of similar duration (9 days) conducted in mice also identified a LOAEC of 10 mg/m^3. Effects observed included minimal interstitial thickening, accumulations of mononuclear cells and slight lymphoid tissue hypertrophy in the lungs.

In a 4-week inhalation study, female rats were exposed to 0, 0.1, 1 or 10 mg/m^3 of quartz 6 hours/day, 5 days/week. Bronchoalveolar lavage fluid was evaluated at 1, 8, and 24 weeks after exposure. Elevated levels of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

granulocytes and significant elevation of markers of cytotoxicity (Lactate dehydrogenase [LDH] and β-glucuronidase [β-glu]) were observed at 1 mg/m^3 and higher. The increased levels of LDH and β-glu were only significant at 24 weeks after exposure. A LOAEC of 1 mg/m^3 was identified at 24 weeks.

Male rats (4 animals per dose) were exposed to 0 or 3 mg/m^3 of cristobalite via inhalation for 6 hours/day, 5 days/week during 13 weeks. Pulmonary inflammation and fibrosis were observed in the exposed group at the end of treatment. When mice were similarly exposed to 5 mg/m^3 of quartz for 6 hours/day, 5 days/week for 15 or 27 weeks, the authors observed increased spleen weight and formation of plaque in the spleen.

In two separate studies, in which rats or hamsters were exposed to quartz via inhalation for at least 6 months, LOAECs of 2 and 3 mg/m^3 were identified, respectively. All the effects observed were related to inflammation and fibrosis of the lung tissue.

Several chronic studies investigated exposure of the respirable forms (i.e. accumulated via inhalation in the lung tissues) of quartz and cristobalite to rats, mice and hamsters. The following is a description of the study in which the lowest non-neoplastic LOAEC was determined. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz, containing 74% of respirable quartz, through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. The mean mass of particle at the end of the exposure period was 0.91 mg/lung. The LOAEC identified was 0.74 mg/m^3 (adjusted for 74% respirable quartz) based on lipoproteinosis, multifocal, inflammatory cell infiltrate and alveolar hyperplasia.

Human epidemiology data

In humans, the lowest observed adverse effect level was identified in a U.S. cohort study. The study was conducted on 3330 gold miners (all are males), who had an average of 9 years underground exposure during the period 1940 to 1965. The cohort was followed up through 1990. Silicosis[1] was identified through death certificates or chest X-rays. A job-exposure matrix together with work history was used to estimate individual exposure. The total silica content in the respirable dust in the mine was estimated at 13% and the median crystalline silica exposure was 0.05 mg/m^3. In this sub population of miners, 170 cases of silicosis were identified. The best predictor for risk of silicosis was cumulative exposure, which varied from less than 1% for a 0.5 mg/m^3-year exposure to 68-84% when exposed to more than 4 mg/m^3-year (based on the average daily dust exposure during the workday each year and summed over time for each miner). The main limitations identified by the authors include the limited number of radiographic surveys, the potential bias from death certificates

[1] Silicosis: Lung disease caused by inhalation of crystalline silica dust, and resulting in inflammation and scarring in forms of nodular lesions in the upper lobes of the lungs. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics). It does not follow that a history of exposure to silica necessarily results in silicosis (Nonsilicotics). The typical "Silicotic" lung nodule is shown in Figure 1.

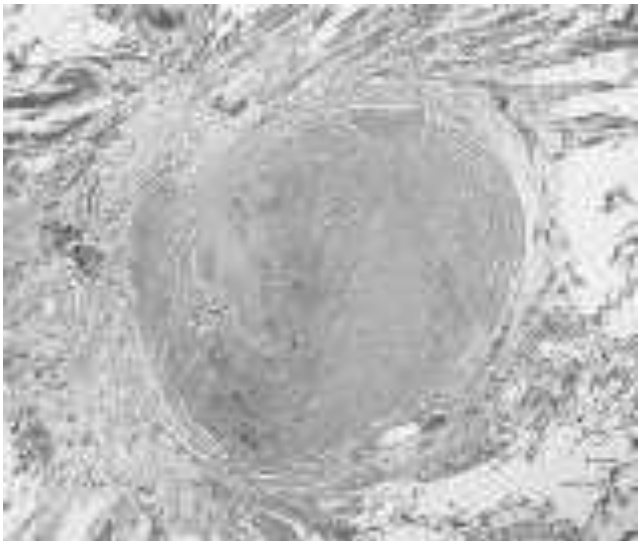

Figure 1. Silicotic nodule characterised by a central zone of hyalinised collagen with a whorled appearance and peripheral dust-containing macrophages (Rees and Murray, 2007).

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

(relying on death certificates instead of relying on repeated x-rays, which were lacking for each miner, may have underestimated the number of cases) and the fact that the conversion of dust counts to

gravimetric measurements may not be accurate based on the estimation of 13% silica content in the respirable dust (although based on a relatively large number of samples (n = 82) collected in two different surveys, there was broad range of content in these samples (1% to 48%, SD = 9), and the percentage of respirable quartz may have differed in earlier years, but data were lacking for these years).

Two other human studies have identified similar LOAECs based on the critical endpoint of radiographic confirmed silicosis. A LOAEC of 0.053 mg/m^3 (mean exposure) was identified in a cross sectional study of South African gold miners and a LOAEC of 0.064 mg/m^3 (mean exposure) was derived in a mining community population-based random sample survey in Colorado.

Carcinogenicity studies

Studies on animals

Experimental studies conducted in rats have shown clear and consistent increases in lung tumours after chronic inhalation exposure. In the nine rat studies identified, five were inhalation studies and four were intratracheal instillation studies. All studies except one inhalation study showed increased incidence of lung tumours. For the inhalation studies with treatment related tumours, concentrations ranged from 1 to 50 mg/m^3 (1, 6, and 30 mg/m^3 of DQ-12 quartz; 12 and 50 mg/m^3 of Min-U-Sil 5 quartz) and duration of exposure ranged from 29 days to 2 years. In the inhalation study with no treatment-related tumours, exposure was 60 mg/m^3 of Sikron F300 quartz for 13 weeks. The following is a description of the neoplastic results in the study also identified as the critical study for non-neoplastic results. Groups of 50 rats/sex were exposed 6 hr/day, 5 days/week for 24 months to filtered air or 1 mg/m^3 of DQ-12 quartz through whole-body inhalation. An additional 50 rats/sex were exposed to 5 mg/m^3 of titanium dioxide as positive controls. In the exposed group, 18 animals developed tumours (12 in females, 5 in males), as opposed to 3 and 2 for the control and positive control groups respectively. The majority (10/18) of the tumours observed were adenocarcinomas. The mean mass of particles in the lungs at the end of the exposure period was 0.91 mg/lung.

For the intratracheal instillation studies, doses ranged from 4 to 57 mg/kg-bw (based on 7, 12 or 20 mg/animal of Min-U-Sil (5) quartz or 20 mg/animal of novaculite quartz). Exposure regimes were diverse and included single instillation with observation for up to two years, to weekly instillation for 10 weeks. It is noteworthy that the single intratracheal administration of a 95% pure quartz particles (<5 μm) resulted in an increased incidence of silicotic granulomas after 3 weeks and lung tumours after 11 months. The most common tumours reported across the long term rat studies were adenocarcinomas, however other tumours such as squamous-cell carcinoma, alveolar carcinoma and bronchiole-alveolar adenoma were also reported, and all animals that developed tumours also showed some degree of fibrosis.

Of particular interest is the intratracheal instillation study, investigating the sequence of pathological events leading to lung tumors. An unspecified number of rats/sex/dose received a single intratracheal instillation of various crystalline silica dusts or ferric oxide, allowing direct administration into the bronchial tree. The doses were 12 or 20 mg of Min-U-Sil 5 quartz (MQZ), 12 mg of hydrofluoric-acid-etched Min-U-Sil 5 quartz (HFMQZ), 12 mg of cristobalite, 12 mg of tridymite and 12 mg of ferric oxide suspended in saline. All groups were observed until six months post exposure, except for both MQZ groups, the HFMQZ and the ferric oxide group which were observed up until 17 months post-exposure. Interim sacrifices were conducted at 6, 11 and 17 months. The rat lungs showed a clear progression of effects. The sequence of pathological events were, an initial inflammatory response leading to a marked hyperplasia and hypertrophy of alveolar cells after one month, and at six months hyperplasia was evident but no lung tumours were observed. In this study, lung tumours were observed starting at the 11 month sacrifice with a 17% and 42% incidence in males and females (based on 3/18 males and 8/19 females), respectively, and at 17 months incidences were 32% and 59% (based on 6/19 males and 10/17 females, respectively). No lung tumours were found in ferric oxide treated rats. Similar studies have also been conducted in hamsters and mice. Although treated mice and hamsters showed treatment related signs (inflammation or fibrosis), no tumours were observed in hamsters. No increase in the incidence of lung tumours was seen in mice treated with quartz; however silicotic granulomas and lymphoid cuffing around airways but no fibrosis were seen in the lungs of quartz-treated mice.

Human epidemiology data

There is an extensive dataset of human studies investigating the link between crystalline silica exposure and cancer. IARC (1997) identified over 50 epidemiological studies based on occupational exposure to dust containing respirable crystalline silica. Main industry sectors from which the human data is derived include gold mines, foundries, granite/stone industry, pottery workers and refractory brick workers. From the least confounded studies, it was noted that lung cancer tended to increase with the following parameters: cumulative

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

exposure; duration of exposure; peak intensity of exposure; presence of radiographically defined silicosis; and length of follow-up time from date of silicosis diagnostic. By definition, clinically or pathologically diagnosed silicosis implies prior exposure to silica (Silicotics).

Since the 1997 IARC report, a large number of epidemiological studies have been published, with the more recent studies being updates from supplementary follow-up of results from previously assessed case-control studies cohorts, new results based on refined exposure assessments or adjustment for confounders or meta-analyses of the pooled data from these epidemiology studies

In a meta-analysis of the data from 10 cohort studies of gold, tin and tungsten miners, granite workers, industrial sand, diatomaceous earth and pottery workers with quantitative exposure estimates for crystalline silica were pooled in order to analyse the risk related to lung cancer. The pooled cohort standardized mortality ratio (SMR, against national rates) [See Appendix 1 for definition] was 1.2 (Confidence Interval [CI] 1.1-1.3). The results from the case-control analyses show a statistically significant trend with duration of exposure (odds ratios (ORs) [See Appendix 1] by quintile of cumulative exposure increased from 1.0 to 1.6 [CIs of 0.85 to 2.1] and by quintile of average concentration increased from 1.0 to 1.7 [CIs of 1.1 to 2.3]), supporting the importance of the increasing lung burden of silica in the occurrence of cancer. Overall, the authors concluded that the results support the carcinogenicity conclusion presented by IARC (1997).

To investigate the link between crystalline silica, silicosis and lung cancer, epidemiological data published between 1966 and 2001 were gathered. Over 50 studies were selected and pooled according to type of study and the parameter being linked to lung cancer (i.e. silica exposure, presence of silicosis in subjects). The quality of study, adjustment for confounding factors, co-exposure to other carcinogens and availability of a more recent analysis of a same cohort were taken into consideration in the final selection of the studies. Analysis of the relationship between exposure to silica and lung cancer included 17 cohort and 13 case-control studies. For the analysis of lung cancer versus silicosis, 11 cohort and 5 case-control studies were selected. The third analysis included 6 cohort and 2 case-control studies to evaluate the risk of lung cancer in non-silicotics. A random effect model was used to conduct each meta-analysis. Pooled cancer risk ratios (RRs) were 1.32 (CI 1.23-1.41) for crystalline silica exposure, 2.37 (CI 1.98-2.84) for individuals exposed to silica with confirmed silicosis (Silicotics) and 0.96 (CI 0.81-1.15) for individuals with no evidence of silicosis (non-silicotics) with confirmed exposure to silica, supporting the general observation that silicosis has a stronger temporal relationship with crystalline silica exposure and furthermore support the view that a human silicotic response could be a preliminary stage in the development of cancer.

A more recent meta-analysis included 28 cohort, 15 case-control and two proportionate mortality ratio (PMR) [See Appendix 1] studies from a variety of occupational settings conducted between 1996 and 2005. Risk ratios (RRs) were calculated based on type of study and silicosis status using fixed and random effect models (results presented here are from the random model). RRs for all cohort studies was 1.34 (CI 1.25-1.45), and were 1.69 (CI 1.32-2.16) for silicotics, 1.25 (CI 1.18-1.33) for those with undefined silicosis status and 1.19 (CI 0.87-1.57) for non-silicotics. In the case-control studies, the general RR was 1.41 (CI1.18-1.67), and the same sub-groups as mentioned above resulted in RRs of 3.27 (CI 1.32-8.2), 1.41 (CI1.18-1.70) and 0.97 (CI 0.68-1.38), respectively. The proportionate mortality ratio for the last two studies was 1.24 (CI 1.05-1.47). The authors noted that the association between lung cancer and exposure to crystalline silica was more consistent for silicotics, i.e., those diagnosed with silicosis and RR values split into type of occupational settings in which participants worked.

Based upon the above three meta-analysis studies and the epidemiology studies discussed in IARC (1997), the following can be concluded. Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis. Cancer risk is often more significant in workers exposed to crystalline silica over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours. Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles.

There have been reports of tumours outside of the lungs in persons with high silica exposure; however, these reports are sparse and the data inconsistent and have not been unequivocally linked to exposure to either one of the crystalline forms (quartz or cristobalite). Some of the reported locations are: oesophagus, stomach, liver, skin and bone. Sufficient epidemiological or toxicological data do not currently exist for quantitative assessment of the exposure-response relationship on these other tissues or organs.

Genotoxicity

Potential genotoxicity has been assessed in multiple *in vitro* and *in vivo* assays. Table 1 below gives a brief summary of the positive results observed in each type of assay.

Table 1. Summary of positive results over total number of results for each assay and each category (all studies

a. one assay conducted with crystalline silica: cristobalite
b. one assay conducted with "ultrafine crystalline silicon dioxide".
c. crystalline silica: tridymite
d. crystalline silica dust (subtypes not provided).

All the *in vivo* human genotoxicity studies are based on three independent studies that used blood samples from workers from diverse occupational settings with confirmed exposures to crystalline silica dust; however, quantification of exposure was not provided. After stratification by smoking status, sister chromatid exchange remained statistically significant in both smokers and non-smokers although the frequency was higher in smokers. For the chromosome aberration assay conducted as part of the same study (blood samples from workers in the stone crusher industry), the increased frequency was no longer significant after stratification. In the DNA damage study of foundry and pottery workers and the micronucleus assay of workers involved in sandblasting and related jobs, results were positive when compared to controls. However, in both studies, smoking status influenced the results, contributing to the increased DNA damage observed since results were greater in smokers versus non-smokers, and the frequency of micronuclei in nasal epithelial cells was higher in smokers (p=0.002) but when using peripheral blood lymphocytes did not differ statistically between smokers and non-smokers who were similarly exposed to silica dust,

The role of *in situ* generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) has been well established in the following types of DNA damage: small scale insertions, DNA base pair deletion, base modification, chromosomal change/loss, microsatellite instability, DNA strand break, 8-hydroxydeoxyguanosine (8-OHdG) mutation and point mutations. ROS and RNS generation is postulated to be (a part of) the DNA damage mechanism for crystalline silica. Studies are described below to support this hypothesis.

DNA was exposed *in vitro* to various crystalline silica dusts, to H_2O_2, or to both. Results show that DNA damage was limited when dust or H_2O_2 were administered alone but increased with the co-exposure. When the reactive oxygen scavenger, dimethylsulfoxide, was added to the test system, DNA strand break was inhibited, data supporting the viewpoint that it is the presence of radicals generated in response to quartz and cristobalite that causes the DNA damage and not quartz or cristobalite themselves.

Hprt mutation assays in rat alveolar epithelial cells, both *in vitro* and *in vivo,* were positive in response to quartz. The positive results *in vivo* were seen only in the presence of significant inflammatory responses in the treated animals. Also, in a parallel *in vitro* experiment, rat alveolar epithelial cells were incubated with the bronchoalveolar lavage fluid from the rats exposed to quartz. Both macrophage and neutrophil enriched lavage cells induced mutation in the exposed alveolar epithelial cells. Addition of catalase (an enzyme which inactivates H_2O_2) before incubation inhibited the increase in *hprt* mutation.

Rats were exposed to either crystalline or amorphous silica in a manner to induce the same level of

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inflammation in the lungs. The inflammatory response was assessed by measuring the proportion of neutrophils in the bronchiolar lavage fluid. The actual concentrations were 3 and 50 mg/m^3 for crystalline and amorphous silica respectively. The animals were exposed for 13 weeks. *Hprt* mutation frequency was measured in the alveolar epithelial cells at the end of the exposure period. Mutation frequency was greatly increased only in the crystalline silica treated rats; no treatment related increase was found in the rats treated with the amorphous form.

In an 8-OHdG assay conducted to monitor DNA damage by reactive oxygen species, female rats were exposed to 0, 0.3, 1.5 and 7.5 mg/animal of quartz via intratracheal instillation. Effects were observed 90 days post-exposure. A clear dose-response relationship was identified between quartz exposure and various inflammation markers (differential cell count, protein, lung surfactant lipids and tumour necrosis factor alpha). Inflammation was present starting at the lowest dose. However, 8-OHdG showed a statistically significant increase starting at 1.5 mg/animal only. Similarly, in another study, 8-OHdG and DNA strand breaks were observed at concentrations of or above 10 ug/m^3 in rat lung epithelial cells.

In the aim of investigating the role of ROS in lung carcinogenesis, rat lung epithelial cells were incubated with polymorphonuclear (PMN) leukocytes (involved in the inflammatory process and responsible for the release of certain ROS) or hydrogen peroxide. Statistically significant increases in 8-OHdG were observed in the presence of PMN or hydrogen peroxide in a dose-response manner.

In a series of experiments which used *in vitro* stimulation of macrophages with crystalline silica and *in vivo* intranasal instillation of crystalline silica in mice, it was demonstrated that that the chronic fibrosis seen in a murine model of silicosis *in vivo* is dependent on the presence of adaptor molecule ASC and Nalp3 inflammazome. These data support a potential mode of action whereby silica triggers cellular responses that in turn activate alveolar macrophages, resulting in an inflammatory response and silicosis. In mice deficient in Nalp3 inflammazome, the development of inflammation and collagen deposition was significantly reduced compared with normal mice 3 months after the initial intranasal instillation of silica.

Analysis of Lung Tumour Data

The weight of evidence for both rats and humans indicates that fibrotic and silicotic lesions in the lung result from inhalation exposure to crystalline silica and that lung cancer is secondary to those lesions in the lung. Although the mechanism of induction for the lung tumours has not been fully elucidated, there is sufficient supportive mode of action evidence from the data presented to demonstrate that a threshold approach to risk assessment is appropriate based on an understanding of the key events in the pathogenesis of crystalline silica induced lung tumours. The body of evidence include the following:

- In experimental studies, all rats that developed tumours also showed fibrosis.
- Adenocarcinomas, the most common type of tumour identified in rats, are commonly associated with fibrosis and deeply scarred lung tissue.
- Experimental rat studies showed a clear progression of the effects from initially mild inflammation, followed by fibrosis over-time, leading eventually to lung tumours.
- Tumours are not present in all treated species dosed in the same way.
- The tumours, both in rats and humans, are concentrated in the lungs only, although other organs are indirectly exposed.
- In human studies, cancer risk is often more significant in workers exposed over a 20 year period or to higher cumulative exposure levels; however a consistent finding is that the onset of silicosis, requires a smaller lag period than that for the appearance of tumours.
- Similarly, cancer risk is often more significantly associated at higher quintiles of exposure compared to the lower quintiles
- Lung cancer rates are higher in workers confirmed to have silicosis versus similarly exposed workers that do not have silicosis.
- For genotoxicity, in vitro results were mostly mixed and in vivo results were mostly positive. However, the vast majority of the positive genotoxicity assay results can be explained by the generation of reactive oxygen species, as demonstrated experimentally, where ROS scavenging prevents the genotoxicity.
- *In vivo*, macrophage deficient mice (macrophages produce ROS in response to crystalline silica) do not develop silicosis nor do they develop tumours and the Nalp3 inflammazome, a key player in the macrophage initiated inflammatory response, is required for the development of pulmonary fibrosis after

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

inhalation of silica.

- Though inhalation exposure to crystalline silica in multiple occupational settings is clear, the increase in risk, based on the several recent meta-analyses of the multiple human epidemiological studies, remains low.

It is worth noting that where aggressive engineering controls have been made to reduce silica dust levels in the workplace (Sweden), silicosis has been eliminated. By corollary, existing exposures outside of the workplace in such areas do not pose a risk for silicosis to the general population.

The respirable forms of quartz and cristobalite possess properties indicating a hazard for human health (repeated dose toxicity, carcinogenicity and genotoxicity). The mode of action in the lungs involves irritation, inflammation and reactive species formation, leading to silicosis, and eventually to tumour formation.

Exposure

Uses

Consistent with oxygen and silicon being the two most abundant elements in the Earth's crust, silicon-oxide minerals, including quartz are ubiquitous in the natural environment. In particular, as a component of sand, quartz may find use in a diverse array of applications. Several high volume uses include, but are not limited to, the use of sand as a filling material for the construction of roads and in general building activities, the use of sand and gravel aggregates as abrasives on roads in winter and the use of fly-ash, which may contain 4-14% quartz and 0.5-1% cristobalite, as a cement additive. These abrasives when used on winter roads are usually mixed with road salts and may be sand only, stone dust, sand and gravel aggregates, or pre-treated sand. They are used mainly by rural municipalities or in areas where cold temperatures diminish the efficiency of salts for de-icing. Quantities of abrasives used in Canada were 5.73×10^9 kg, 4.59×10^9 kg, and 4.93×10^9 kg for 2007, 2008 and 2009, respectively.

Industrial sand, high purity silica sand products with closely controlled sizing are expected to contain quartz and cristobalite, include lump silica (2-3mm up to 15 cm or more), silica sand (75µm to 2-3mm) and silica flour (less than 75µm). Lump silica may be used in the production of silicon alloys, silica bricks, and the linings of certain types of pulverizers (eg. ball mills and tube mills).

Silica sand may be used in the manufacture of glass and glass fibres, silicate chemicals and silicon carbide, the hydraulic fracturing of wells, foundry moulding, and for sandblasting. Silica flour may find use in the ceramics and cement industries, as a filler and extender in rubber and coatings, and as an abrasive in soaps.

Natural clays, such as bentonite and fuller's earth, are used in cat litters for their high water absorbance capacities. Quartz is a natural component of these clays, and consequently, it may be present in cat litter products. High purity α-quartz is a piezoelectric material, which means that application of a voltage induces a distortion in the crystal shape and vice versa. This ability to interconvert electrical and mechanical energy has led to the use of quartz crystals in electronic devices requiring precise timing control, for example telephones, radios, watches and computers.

According to a survey conducted in Canada, quartz and cristobalite are also used in abrasives, adsorbents, filter products (diatomaceous earth), grout and cement. These substances reportedly also find use as fillers, which add bulk and improve wear resistance, in paints and coatings, adhesives, sealants, polymer films, caulking, epoxy resins and silicones. Also, quartz is listed as an ingredient in 60 cosmetic products in Canada. The types of products include anti-wrinkle preparation, eye and face makeup, lipstick, hair dyes, shampoos and grooming products, as well as skin cleansers, moisturizers and tanning preparations.

Natural Sources

In Canada, quartz naturally occurs in many types of rock formations. Those with high silicon dioxide content (95% SiO_2 or more) include vein and massive intrusion bodies, quartz pebbles, silica sand, sandstone and quartzite. Sandstone is a sedimentary rock mostly composed of quartz grains cemented by a bonding material such as clay, calcite or iron oxide. Quartzite is a hard, compact, metamorphosed sandstone made of grains of quartz firmly bonded with a siliceous cement. Mineral aggregates (e.g., sand and gravel) have variable silicon dioxide content. Quartz is also found as crystals, aggregates or discrete particles in certain igneous rocks (e.g., granites and pegmatites), soils, sediments, air and surface water. This omnipresence is consistent with the fact that silicon is the second most abundant chemical element on Earth.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

Cristobalite is naturally produced in the ashes of volcanic eruptions, and by combustion metamorphism which is a local phenomenon of spontaneous combustion of naturally occurring substances such as bituminous rocks, coal or oil. It may be found in cavities in volcanic rocks and in thermally metamorphosed sandstones and may also be a transient stage in the diagenesis of diatomaceous shale with the result that soils made of these geologic formations may be rich in cristobalite. Unlike quartz, the natural occurrence of cristobalite is limited to specific geographic regions and mineral types.

Anthropogenic Sources

Natural quartz is isolated from ore via beneficiation, which involves milling or grinding the material into particles that are separated into desired mineral and waste. The materials obtained are either used directly or further purified. In Canada, in 2006, 2.146×10^{9} kg of pure quartz were mined, and 2.385×10^{11} kg of sand and gravel aggregates were produced. The proportion of quartz in silica sand deposits and gravel aggregates will vary from one site to another.

Cristobalite can form from silica melts during the preparation of silica glass; quartz is not obtained from melts but is manufactured at elevated temperature and pressure via a hydrothermal process. Cristobalite also forms during the calcination[2] of diatomaceous earth.

Human Exposure Estimate

Ambient air

The exposure assessment is focussed on respirable quartz and cristobalite, which in ambient air comprises a component of total particulate matter (PM). In Canada, data on the concentrations of silicon in PM was available and used as a surrogate for quartz and cristobalite. This approach is conservative because the measured silicon includes all silicon-containing substances and therefore represents the upper limit for quartz and cristobalite in ambient air.

The National Air Pollution Surveillance (NAPS) Program measured concentrations in $\mu g/m^3$ of silicon in PM with aerodynamic radii less than 2.5 µm ($PM_{2.5}$ (dichot)), and from 2.5 to 10 µm (PM_{10} (dichot)) (the total particulate matter with aerodynamic radii less than 10 µm (PM_{10}) is obtained by adding these values) in Canada. In 2009, as part of the NAPS Program, silicon concentrations were determined on over 1600 samples of $PM_{2.5}$(dichot) and over 1500 samples of PM_{10}(dichot) at 24 urban locations across Canada. An estimate of exposure to quartz and cristobalite can be obtained by assuming that all the silicon in the PM is represented stoichiometrically as SiO_2, and multiplying the reported concentration of silicon by 2.14 to obtain a value for silica.

The intake of respirable quartz and cristobalite by the general population of Canada is estimated using a range covering the lowest 50^{th} percentile SiO_2 concentration in PM_{10}, measured in Pt. Petre, ON, (0.12 $\mu g/m^3$) to the highest 50^{th} percentile concentration in PM_{10} measured in Calgary, AB (2.1 $\mu g/m^3$). The 50^{th} percentile SiO_2 concentrations ranged from 0.1 to 2.1 $\mu g/m^3$ across the survey sites; the top of this range is quite close to the average of the maximum values for the 24 sites (3.7 $\mu g/m^3$). The outdoor data were used to represent the indoor levels, because information on indoor silicon concentrations was not available, and the range of PM_{10} measured indoors is generally lower than the outdoor range. Thus, this approach conservatively overestimates indoor exposure in homes.

The highest exposure group based on these calculations is children ages 0.5 to 4 years with an estimated daily intake ranging from 0.07 to 5.26 µg/kg-bw per day; the estimated daily intake decreases with age due to changes in the ratio of inhalation rates to body weights; the daily intake of adults, 20-59 years old, is estimated to range from 0.03 to 2.00 µg/kg-bw per day.

Consumer Products

Exposure to respirable quartz from the use of cosmetic products, which contained quartz as an ingredient, was considered low because they are not formulated for spray application, the loose powders were reported to contain less than 0.1% quartz, and in these products the substance is not expected to be associated with other components of the formulation and not available in a free form.

For consumer Do It Yourself (DIY) activities around the home, the highest mean breathing zone concentration of particles from sanding dry wall (median cut-point of 10µm) of 6.31 mg/m^3, was used to derive an upper-

[2] Calcinations: Heat treating a substance, but without fusion, to bring about change in its physical or chemical constitution.

This document may only be reproduced integrally. The conclusions in this document are intended to be mutually supportive, and should be understood and interpreted together.

bound exposure estimate ranging from 2 to10 µg/kg-bw per event.

Quartz is used to formulate a large number of paints and coatings. To estimate potential inhalation exposure to quartz from these products, the spray painting of wall paints with an airless spray gun was considered appropriate as a conservative scenario. Exposure to respirable paint particles was estimated using data from controlled a laboratory study in which walls of poorly ventilated test rooms were painted by professional painters using an airless sprayer to apply interior latex paint. The maximum concentration of 13% quartz in paint in Canada was used to estimate exposure. The upper-bound estimate of exposure to quartz, based on the maximum concentration of 13% quartz in paint in the Canadian market and the maximum concentration of respirable paint particles measured in these controlled studies when recommended personal protective equipment is used, is 0.954 µg/kg-bw per event.

Inhalation of ambient air containing quartz and cristobalite is the dominant pathway of chronic exposure (excluding that from DIY activities) for the general population. Because SiO_2 makes up only approximately 5% of PM_{10}, silicon concentrations (expressed as SiO_2) measured in the Canadian NAPS survey of 24 urban locations were considered most relevant to the estimation of exposure by the general population. Quartz and cristobalite comprise only a portion of the total SiO_2 in PM_{10}, therefore, the use of the total silicon concentration to represent the upper bound crystalline silica concentrations results in an overestimation of exposure.

Appendix 1: Definitions of Epidemiological Terms in the ITAP

SMR (Standardized Mortality Ratio): The ratio (x 100) of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.

OR (Odds Ratio): In epidemiological case-control studies, a relative measure of disease occurrence. The odds in favour of a particular disease occurring in an exposed group are divided by the odds in favour of its occurring in an unexposed group. If the condition being studied is rare, the odds ratio is a close approximation to the relative risk.

RR (Risk Ratio): The probability of the occurrence of a disease in a group that has been exposed to some environmental, medicinal, microbial, or toxic influence, relative to its probability in a randomly selected population.

PMR (Proportionate Mortality Ratio): Proportionate mortality is the proportion of deaths in a specified population over a period of time attributable to different causes. Each cause is expressed as a percentage of all deaths, and the sum of the causes must add to 100%. These proportions are not mortality rates, since the denominator is all deaths, not the population in which the deaths occurred. Thus, proportionate mortality ratio is a measure of the frequency of occurrence of the proportionate mortality in a defined population during a specified interval of time.

Toxicity Profile

Ethylene glycol
(CAS No. 107-21-1)

Ethylene glycol has been reviewed in the OECD-SIDS program (OECD, 2004a,b).

Toxicokinetics/Metabolism

Ethylene glycol is almost completely absorbed by laboratory animals via oral routes as would be expected from their total miscibility with water. In *in vivo* rodent dermal absorption studies, 1-51% of ethylene glycol was absorbed. Since ethylene glycol is completely soluble in water, it is expected to be well distributed throughout the aqueous tissues of the body with lower concentrations in adipose tissue. Uniform distribution has been demonstrated to a limited extent for ethylene glycol. The main metabolic pathway for metabolism of ethylene glycol is oxidation via alcohol dehydrogenases and aldehyde dehydrogenases. The main metabolites of ethylene glycol are carbon dioxide, oxalic acid and glycolic acid. Ethylene glycol may be directly eliminated by urinary excretion. Acid metabolites of ethylene glycol are also eliminated in urine and may also be metabolized to carbon dioxide and eliminated in exhaled breath.

Acute Toxicity

The oral LD_{50} values range from 589 to 13,400 mg/kg for rats (OECD, 2004b), 800 to 15,280 mg/kg for mice (OECD, 2004b), 661 to 11,000 mg/kg for guinea pigs (OECD, 2004b), and 5,000 mg/kg for rabbits (OECD, 2004b).

Irritation

Ethylene glycol was not irritating to rabbit skin (Guillot *et al.*, 1982), but there was some indication of irritation in a human primary irritation patch test (OECD, 2004b). It was not an eye irritant to rabbits (Guillot *et al.*, 1982).

Sensitization

Ethylene glycol was not a skin sensitizer to guinea pigs (Kurihara *et al.*, 1996).

Repeated Dose Toxicity (Oral Studies only)

Male and female Fischer 344 rats were given in their feed 0, 40, 200 or 1,000 mg/kg ethylene glycol for 24 months. At 1,000 mg/kg, the following effects were seen in males:

increased neutrophils, blood urea nitrogen, serum creatinine, urine volume, urine calcium oxalate crystals, water consumption rates, kidney weight (absolute and relative), mortality, mineralization of the heart, lungs, stomach, vas deferens and urinary system pathologic changes; decreased red blood cells, hematocrit, hemoglobin, serum glutamic pyruvic transaminase, mean corpuscular volume, urine specific gravity, urine pH, liver weight (absolute and relative), body weight gain, and life span. At the highest dose, the following effects were seen in females: increased mean corpuscular volume, urine specific gravity, urine calcium oxalate crystals, urine uric acid crystals, and kidney weight (absolute and relative); and decreased mean corpuscular hemoglobin concentration, urine pH, and urine volume. The NOAEL for this study is 200 mg/kg/day (DePass *et al.*, 1986a).

Male Wistar rats were given in their feed 0, 50, 150, 300 or 400 mg/kg ethylene glycol for one year. At the higher dose levels (300 and 400 mg/kg), the histopathological observations included basophilic foci of crystaluria-related nephropathy, renal tube dilation, bifringent crystals morphologically representative of calcium oxalate, dilation of the renal pelvis, and transitional cell hyperplasia in the renal pelvis or bladder. To determine renal effects, the severity of nephropathy in the kidney sections was graded on a scale of 0 to 5, with 0 representing no crystal nephropathy and 5 representing end-stage nephropathy indicative of impending renal failure. Ethylene glycol related nephropathy was not present in the kidney sections from the control group or the lower doses (50 and 150 mg/kg). In the 300 mg/kg group, severity grades ranged from 1 to 4 with the mode of occurring at 1 (minimal). In the 400 mg/kg group, severity grades ranged from 3 (moderate) to 5 (end-stage) with the mode at 4 (marked). The NOAEL for this study is 150 mg/kg/day (Wilson *et al.*, 2005).

Male Fischer 344 and Wistar rats were given in their feed 0, 150, 500 or 1,000 mg/kg ethylene glycol for 16 weeks. At 1000 mg/kg, the following effects were seen: mortality in Wistar strain (2/10) with prior clinical observations of emaciation and dermal atonia and macroscopic findings of changes in kidneys (pale, calculi) and small seminal vesicles in these animals; mean body weight losses, lower mean body weights and mean cumulative body weight changes in Wistar strain (weeks 2 – 16); lower mean food consumption in Wistar strain; higher mean water consumption in both F344 and Wistar strains; lower mean specific gravity and higher mean total urine volume in both F344 and Wistar strains; macroscopic findings of pale kidneys, presence of calculi, rough surface and dilated pelvis; higher mean absolute and relative kidney weights in both F344 and Wistar strains; renal macroscopic findings of crystal nephropathy in Wistar and F-344 rats, with more severe nephropathy in Wistar strain than in the F344 strain. At 500 mg/kg, the following effects were seen: lower mean body weights (study weeks 3, 6-8, and 10-12) and mean cumulative body weight changes in the Wistar strain throughout the study with slightly lower mean food consumption throughout the study; higher mean water consumption in the Wistar strain; lower mean urine specific gravity and higher mean total urine volume in the Wistar strain; macroscopic findings in the Wistar strain consisting of predominantly pale kidneys, presence of calculi, rough surface, and dilated pelvis; higher mean absolute and relative kidney weight in the Wistar strain; renal macroscopic findings of crystal nephropathy in Wistar and F-344 strains, with more

severe nephropathy in the Wistar strain than in the F344 strain. The NOAEL in both the F344 and Wistar rats is 150 mg/kg/day (Cruzan *et al.*, 2004).

Male and female Fischer 344 rats were given in their feed 0, 0.32, 0.63, 1.25, 2.5, or 5% ethylene glycol for 13 weeks. Mortality was seen in the 5% animals in males, but not in females. Mean weight gain was significantly decreased in the 2.5 and 5% males, while there was no significant differences in female rats. There was no apparent difference in feed consumption between both male and female rats and the control group. There was no significant change in right kidney weight (both sexes), but a significant increase was seen in the left kidney weight in the 2.5 and 5% dose groups (both sexes). Mean thymus ratio to terminal body weight was significantly decreased in the 5% males. Serum urea nitrogen levels were significantly increased in the 2.5 and 5% males, and significantly increased in the $\geq$0.32% females. For both sexes, creatinine levels were decreased in the 0.32% group and significantly increased in the 2.5 and 5% groups. Kidneys from the 2.5 and 5% male rats had rough, granular and/or pitted appearances. Nephrosis was seen only in the 5% females. Brains from the 5% male rats contained clusters of crystals. The NOAEL for this study is 1.25%, which was estimated to be 600 to 1,000 mg/kg/day (Melnick, 1984).

Male and female Sprague Dawley rats were given in their drinking water ethylene glycol for 90 days. The concentrations for females were 0, 0.5, 1.0, 2.0 or 4.0% (0, 597, 1,145, 3,087 or 5,744 mg/kg-day). The concentrations for males were 0, 0.25, 0.5, 1.0 or 2.0% (0, 205, 407, 947 or 3,134 mg/kg-day). Mortality was seen only at the highest dose level for both males and females. Decreased body weights were seen in the highest dosed males. Only males showed any significant changes in organ weights. Kidney weights were significantly increased in the 1% and 2% males, which heart, liver, and lung were significantly decreased in the 2% males. There was also a significant increase in the ratio to body weight for the brain and gonads of the males in the highest dose group. Leukocyte levels were significantly decreased in the 0.5, 2 and 4% females, but not in males. LDH, creatinine, ALT, calcium and glucose were significantly different in the 1% males, and phosphorus, BUN, and creatinine in the 2% males. There were significant increases in phosphorus in the 1% females and glucose in the 0.5 and 4% females. Kidney lesions were seen in the $\geq$2% females and in the $\geq$1% males. Lesions were more prominent in males than in females. Renal changes consisted of tubular dilation, tubular degeneration, acute inflammation, birefringent crystals in tubules and pelvic epithelium. The NOAEL for this study is 407 mg/kg-day for males. The LOAEL for females is 597 mg/kg/day; a NOAEL was not established (Robinson *et al.*, 1990).

Male and female Sprague-Dawley rats were given in their feed 0, 0.1, 0.2, 0.5, 1.0 or 4.0% ethylene glycol for two years. There was significant reduction in growth in the 4% males after week 16, and in the 1% males after week 70. The 4% females did not gain any weight past the first year of the study. Water consumption was double that of the controls in the 4% males that initiated soon after the start of the study. The 1% males had significant increases in water consumption after 6 months and some increase was observed in the 0.5% males. Females only showed increased water consumption in the 4% group. There was 100% mortality in the 1 and 4% males, while mortality of

additional dose levels were below that of the controls. There was 100% mortality in the 4% females, while the 1% females were similar to the controls; the 0.1, 0.2 and 0.5% females were increased compared to the controls. Since the 1 and 4% males and the 4% females all died before the study termination date, there are no data for these groups on terminal organ weight. For males, the terminal organ weights were decreased in all dose levels compared to the controls. For females, the organ weights were similar to the controls. The 1 and 4% males and females had kidneys with stones and crystals. The NOAEL for this study is 0.2% (data was insufficient to calculate the dose) (Blood, 1965).

Male and female B6C3F_1 mice were given in their feed 0, 0.32, 0.63, 1.25, 2.5, or 5.0% ethylene glycol for 13 weeks. There was no mortality for either male or female mice at any dose level. No clear dose-related effect was seen in mean weight gain, and there was no clear evidence of decreased feed consumption. There was no significant change in organ/body weight ratio for either sex for any dose level. Serum urea nitrogen and creatinine levels were unaffected. Kidney lesions were observed in half of the male mice in the 5% dose level and one mouse in the 2.5% dose level. Lesions were tubular dilation, cytoplasmic vacuolization, and regenerative hyperplasia. There was no evidence of crystal formation in the tubules. No kidney effects were seen in the female mice. Degenerative change was present in the livers of all male mice in the 2.5 and 5% dose levels. The NOAEL for this study is 1.25%, which was estimated to be 600 to 1,000 mg/kg/day (Melnick, 1984).

Male and female B6C3F_1 mice were given in their feed 0, 6,250 ppm (males only), 12,500 and 25,000 ppm (males and females) or 50,000 ppm (females only) for 103 weeks. These concentrations are approximately equivalent to 0, 1,500, 3,000, 6,000 or 12,000 mg/kg-day. There was no statistically significant difference in survival between dosed and control groups. Mean body weight and food consumption of mice administered ethylene glycol were generally similar to those of controls throughout the study. No chemical-related clinical findings were observed. Liver lesions (in male mice) and arterial hyperplasia (in females) were observed at 12,500 ppm, but no adverse effects were observed at 6250 ppm. The NOAEL for this study is 1,500 mg/kg/day (NTP, 1993).

Genotoxicity

Mutagenicity studies in bacteria and *in vitro* mutagenicity studies in mammalian cells have been uniformly negative (OECD, 2004a,b). The results of *in vitro assays* of ethylene glycol for chromosomal aberrations (CHO chromosomal aberration and sister chromatid exchange assays) have also been uniformly negative (OECD, 2004a,b).

Ethylene glycol was equivocal when tested in an *in vivo* mouse bone marrow micronucleus study (Conan *et al*., 1979). There were some findings of statistically significant increases in micronuclei, but no dose-related trends and potential confounding due to toxicity (lethality) at high doses. Ethylene glycol did not increase the incidence of chromosomal aberrations in mice *in vivo* (Conan *et al*., 1979). An *in vivo* rodent

dominant lethal mutagenesis assay conducted at doses up to 1,000 mg/kg in Fischer 344 rats was negative (DePass *et al*., 1986b).

Carcinogenicity

Male and female B6C3F_1 mice were given in their feed 0, 6,250 ppm (males only), 12,500 and 25,000 ppm (males and females) or 50,000 ppm (females only). These concentrations were approximately equivalent to 0, 1,500, 3,000, 6,000 or 12,000 mg/kg-day. Body weights, survival, and incidence of tumors were similar between treated and control mice (NTP, 1993).

Reproductive Toxicity

Ethylene glycol has been assessed by the Reproductive Assessment by Continuous Breeding (RACB) protocol in which parental mice received chemical via drinking water during pre-mating exposure, cohabitation, pregnancy, and lactation. The F_1 generation received prenatal exposure via maternal exposure during gestation, with the exposure continuing during lactation, weaning, and mating of F_1 animals and production of an F_2 litter. The doses were 0, 0.25, 0.5 or 1% ethylene glycol, which corresponded to approximately 0, 410, 840 or 1,640 mg/kg/day. No adverse effects were noted in the parental animals at doses up to 1%. There was a small, but statistically significant, effects on the numbers of litters per fertile pair, the number of live pups per litter, and live pup weight in the 1% dose group. Neither the 0.25 nor 0.5% dose groups were significantly affected. The number of live pups per litter was lower in the treated group, but differences were not statistically significant. Unusual facial features (*i.e.*, shorter snout and wide-set eye) and skeletal defects (shortened frontal, nasal, and parietal bones; fused ribs abnormally shaped or missing sternebrae, abnormally shaped vertebrae; and twisting of the spine at 1%) were noted on some of the offspring of the treated mice, but not in the controls. The parental NOAEL is 1% (approximately 1,640 mg/kg/day), and the NOAEL for reproductive toxicity is 0.5% (approximately 840 mg/kg/day (Lamb *et al*., 1985).

In a three-generation reproductive toxicity study, Fischer 344 rats were given in their diet 0, 40, 200 or 1,000 mg/kg/day ethylene glycol. There were no treatment-related effects on clinical signs of toxicity or survival in the parental animals. There were no significant effects on fertility index, gestation index, gestation survival for all three generations. Mean pup weights in the all three generations were similar between treated and control animals. The NOAELs for parental and reproductive toxicity are 1,000 mg/kg/day (DePass *et al.*, 1986b).

Developmental Toxicity (Oral and Dermal Studies only)

Pregnant Sprague-Dawley rats were dosed by oral gavage with 0, 50, 150, 500, 1,000 or 2,500 mg/kg ethylene glycol during gestational days (GD) 6-15. Maternal toxicity was

observed in the 2,500 mg/kg group and consisted of significantly decreased body weights, increased water consumption, decreased uterine weights, increased kidney weights, and increased relative liver weights. At 500 mg/kg, there were developmental effects, which included reduced fetal body weights, extra or missing ribs, missing arches, and poor ossification in thoracic and lumbar centra. In the 2500 mg/kg group, in addition to skeletal malformations, there was gastroschisis, hydrocephaly, lateral ventricle dilated (tissue depressed), umbilical hernia, and atelectasis. The NOAELs for maternal and developmental toxicity are 1,000 and 500 mg/kg/day, respectively (Neeper-Bradley *et al.*, 1995).

Pregnant CD rats were dosed by oral gavage with 0, 1,250 2,500 or 5,000 mg/kg ethylene glycol during GD 6-15. In the $\geq$2,500 mg/kg groups, the dams had increased relative kidney weights, decreased gravid uterine weight, and increased water consumption. Maternal body weight gain was significantly decreased in the 1,250 mg/kg group. Live litter size was significantly decreased in the 5,000 mg/kg group, and fetal body weights were decreased in the 1,250 and 5,000 mg/kg groups. Litters with malformed fetuses were observed in the $\geq$1,250 mg/kg groups. The LOAELs for maternal and developmental toxicity are 1,250 mg/kg/day; NOAELs were not established (Price *et al.*, 1985).

Pregnant Fischer 344 rats were given by oral gavage 0, 40, 200 or 1,000 mg/kg ethylene glycol during GD 6-15. No maternal toxicity was observed at any dose level. There were no significant effects on preimplantation loss, fetal length, fetal weight, total implantations or litter size. There was an increased incidence of skeletal alterations in the 1,000 mg/kg group, which consisted of poorly ossified and unossified vertebral centra. No significant increases in the incidence of major malformations were observed. The NOAELs for maternal and developmental toxicity are 1,000 and 400 mg/kg/day (Maronpot *et al.*, 1983).

Pregnant CD-1 mice were dosed by oral gavage with 0, 50, 150, 500 or 1,500 mg/kg ethylene glycol during gestational days (GD) 6 to 15. There was no maternal toxicity. At 1,500 mg/kg, there were reduced fetal body weights, fused ribs and arches, poor ossification in thoracic and lumbar centra, and increased occurrence of an extra 14^{th} rib. At 500 mg/kg, there was slight reductions in fetal body weight and increased incidences of extra ribs. The NOAELs for maternal and developmental toxicity were 1,500 and 150 mg/kg/day, respectively (Neeper-Bradley et al., 1995).

Pregnant CD-1 mice were dosed by oral gavage with 0, 750, 1,500 or 3,000 mg/kg ethylene glycol during GD 6 to 15. There was a significant decrease in maternal gain, gravid uterine weights, and liver weights in the 1,500 mg/kg group. A decreased number of implantation sites per litter was observed in the 1,500 mg/kg group. Significant decrease in liver litter size was observed in the 3,000 mg/kg group and decreased fetal body weights were seen at $\geq$750 mg/kg. Litters with a significant increase in malformed fetuses were observed in the $\geq$750 mg/kg groups. There was a significant dose-related increase in postimplantation loss per litter, though there were no significant pairwise comparisons. The NOAEL for maternal toxicity is 750 mg/kg/day;. The LOAEL for

developmental toxicity is 750 mg/kg/day; the NOAEL was not established (Price *et al.*, 1985).

In a short-term reproductive and developmental toxicity screen test, male and female Swiss Crl:CD-1 mice were allowed to mate over a three-day period. The males were dosed by oral gavage from study day 3 to study day 20. The Group A females were exposed throughout the 21-day test period; the Group B females were exposed during GD 8-14. The doses were 0, 250, 700 or 2,500 mg/kg ethylene glycol. The Group A females were sacrificed after 19 days of treatment, and the Group B females were allowed to litter and rear to postnatal day (PND) 4. There was no maternal or paternal toxicity. The 2,500 mg/kg females in Group A had significantly fewer liver implants and more dead implants. The 2,500 mg/kg in Group B had significantly lower total litter weights on PND 1 and 4. The NOAELs for parental and developmental toxicity are 2,500 and 700 mg/kg/day (Harris *et al.*, 1992).

In a Chernoff/Kavlock assay, pregnant CD-1 mice were dosed by oral gavage with 0 or 11,090 mg/kg ethylene glycol during GD 7-14. The females were allowed to litter and rear to PND 3. Ten percent of the maternal animals died. The number of surviving pups per litter (40% survived), birth weight and pup weight gain were reduced. The LOAELs for maternal and developmental toxicity are 11,090 mg/kg; NOAELs were not established (Schuler *et al.*, 1984; Hardin *et al.*, 1987).

Pregnant CD-1 mice were administered by dermal application 0, 400, 1,677 or 3,549 mg/kg ethylene glycol during GD 6-15. There was minimal, if any, treatment-related maternal toxicity. Copora lutea, total implants, percentage of live fetuses per litter, fetal body weights, and incidence of external or visceral malformations were unaffected by treatment. There was, however, a significant increase in two skeletal variations in the 3,549 mg/kg group. The NOAELs for maternal and developmental toxicity were considered to be 3,549 mg/kg/day (Tyl *et al.*, 1995).

Key Study/Critical Effect for Screening Criteria

The available data show that repeated oral exposures to ethylene glycol causes primarily kidney toxicity; is also a reproductive and developmental toxicant in rodents when administered at high doses by oral gavage. Rats develop kidney toxicity at substantially lower doses than mice. Among rats, there are differences in the susceptibility of strains towards developing kidney toxicity from ethylene glycol exposure. The renal toxicity of dietary ethylene glycol to rats was clearly related to oxalic acid levels in the kidney, which explained strain differences (Corley *et al.*, 2002). In animals chronically exposed to ethylene glycol histopathologically-detectable kidney damage is believed to be related to oxalate crystals (crystal nephropathy). No adverse chronic renal effects from ethylene glycol dosing were seen in animals exposed below 150 mg/kg/day. The oral RfD for ethylene glycol is thus based on the NOAEL of 150 mg/kg/day from the one-year rat feeding study by Wilson *et al.* (2005).

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 150/100 = 1.5 mg/kg/day

Drinking water guideline value = 5.3 ppm

Toxicity Profile

Guar Gum
(CAS No. 9000-30-0)

Guar gum (CAS No. 9000-30-0) is the milled endosperm of the leguminous plant *Cyanopsis tetragonolobus*. Structurally, it is a galactomannan consisting of a main chain of D-mannose with a side chain of D-galactose at approximately every second mannose unit. The mannose units are β-(l-4) linked, and the single D-galactose units are joined to the main chain by α-(1-6) linkages. The estimated molecular weight of guar gum cranges from 200,000 to 300,000 daltons (Glickman, 1969).

Guar gum is approved for use as a food additive by the U.S. Food and Drug Administration and is on the list of substances "generally recognized as safe" (CFR 1974).

Acute Toxicity

The oral LD_{50} is 8,100 mg/kg for mice and 9,400 mg/kg for rats (Bailey and Morgareidge, 1948).

Irritation

No data were found.

Sensitization

There are reports of respiratory sensitization in workers exposed occupationally to guar gum dusts (Maio, 1986).

Repeat Dose Toxicity Studies

F344 rats and B6C3F_1 mice were given diets containing 0, 6,300, 12,500, 25,000, 50,000 or 100,000 ppm guar gum for 13 weeks (NTP, 1982). Mean body weights were decreased in male rats (100,000 ppm group) and in female mice (50,000 and 100,000 ppm). A dose-related decrease in feed consumption was observed for male and female rats; male and female mice were comparable or higher than that of controls. There were no compound-related clinical signs or histopathological effects.

F344 rats and B6C3F_1 mice were given diets containing 0, 25,000 ppm or 50,000 ppm guar gum for 103 weeks (NTP, 1982). Mean body weights of the high-dose females were

lower than those of the controls after week 20 for mice and week 40 for rats. No compound-related clinical signs or adverse effects on survival were observed. Feed consumption by dosed rats and mice of either sex was lower than that of controls. There were no non-neoplastic histopathological effects in either rats or mice that were treatment-related.

Genotoxicity

Guar gum was not mutagenic to *Salmonella typhimurium* TA 1530 or G-46 when tested without metabolic activation; however, it was mutagenic to *Saccharomyces cerevisiae* D-3 (Green, 1977). Guar gum also was reported to cause chromosomal aberrations in human embryonic lung cells WI-38 (Green, 1977). No *in vivo* genotoxicity studies have been conducted on guar gum.

Carcinogenicity

F344 rats and B6C3F_1 mice were given diets containing 0, 25,000 ppm or 50,000 ppm guar gum for 103 weeks (NTP, 1982). There were increased incidences of adenomas of the pituitary in male rats and pheochromocytomas of the adrenal in female rats that were statistically significant, but these differences were considered to be unrelated to guar gum administration. When pituitary adenomas or carcinomas and when pheochromocytomas or malignant pheochromocytomas are combined, the statistical differences disappear. Hepatocellular carcinomas occurred in treated male mice at incidences that were significantly lower than that in controls. The combined incidence of male mice with either hepatocellular adenomas or carcinomas was also significantly lower in the high-dose group. It was concluded that under conditions of this bioassay, guar gum was not carcinogenic for F344 rats or B6C3F_1 mice.

Reproductive Toxicity

No data were found.

Developmental Toxicity

Female rabbits were given daily (6 hours/day) dermal administration of 0, 2, 10 and 50 mg/kg guar gum during gestational days 6 through 18 (IRDC, 1988). Mortalities included 2 deaths at 50 mg/kg and 1 death at 10 mg/kg. A single animal was killed in extremis. A dose-related increase in dermal irritation (including erythema, edema, and desquamation) was observed in animals receiving 10 and 50 mg/kg. The number of early resorptions was significantly increased and the number of viable fetuses was correspondingly decreased at 50 mg/kg/day ($p<0.05$). The frequency of fetal malformations and variations in the treated groups was comparable to that of the control

group at all dose levels. The NOEL for this study is 2 mg/kg/day.

Key Study/Critical Effect for Screening Criteria

The key studies for the determination of a drinking water guidance value is the NTP two-year chronic bioassays. The LOAELs are based on decreased mean body weights in female mice and rats fed 50,000 ppm guar gum in diet for 103 weeks. The NOAELs for these studies are 25,000 ppm guar gum.

Rat: NOAEL (mg/kg/day) = 25,000 ppm * 0.05 = 1,250 mg/kg/day

Mouse: NOAEL (mg/kg/day) = 25,000 ppm * 0.13 = 3,250 mg/kg/day

Where 0.05 and 0.13 are the fraction of body weight that rats and mice, respectively, consume per day as food (U.S. EPA).

The lowest NOAEL of 1,250 mg/kg/day for the rat will be used to derive a drinking water guidance value.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD = 1,250/100 = 12.5 mg/kg/day

Drinking water guideline = 44 ppm

Toxicity Profile

Hemicellulase
(CAS No. 9025-56-3)

Hemicellulases are a group of enzymes that break down hemicellulose, which are polysaccharides that are present in cell walls of all terrestrial plants. These polysaccharides have a β-(1→4)-linked backbone and are composed of pentoses (xylose, arabinoses), hexoses (mannose, glucose, galactose), and sugar acids. Unlike cellulose which are polysaccharides consisting of linear chains of several hundred to over ten thousand β-(1→4) linked D-glucoses, hemicelluloses are not chemically homogeneous. The best characterized hemicellulases are the 1,4- β -D-xylanases and, in particular, those derived from fungal sources presumably because their substrates, xylans, constitute the largest proportion of hemicelluloses in pasture plants.

No toxicity information could be located on hemicellulases; however, mammalian toxicity information were found on the cellulase enzymes (HERA, 2005). Cellulases cleave the ß-1,4-glycosidic bonds in cellulose, and are used in the pulp and paper industry, the textile industry, and in detergents to remove deposits and stains.

Enzymes are catalytic proteins or polypeptides and consist of amino acid residues coupled via peptide bonds. They are primarily characterized by their biocatalytic or enzymatic activity. There is a broad range of detergent cellulases used both from fungal as well as from bacterial origin; all are characterized by ß-1,4-endoglucanase activity. For the purposes of risk assessment, the structure of hemicellulases would be expected to be similar to that of cellulases, given that hemicellulases and cellulases are both enzyme families that hydrolyze polysaccharides, although differing in their substrates. Thus, the toxicity data on cellulases will be used as read-across to hemicellulases.

Acute Toxicity

The oral LD_{50} of a cellulase enzyme was calculated to be 8,000 mg/kg for mice and >10,000 mg/kg for rats (HERA, 2005). The inhalation LC_{50} of the same cellulase enzyme in rats was >3.48 mg/L. The mass mean diameter was 7.8 μm with a geometric standard deviation of 2.1 μm (HERA, 2005).

Irritation

Cellulase enzymes are mild to non-irritating to the skin and eyes of rabbits (HERA, 2005). However, the irritation potential is dependent on the amount of protease contamination in the enzyme test preparation, particularly with regards to eye irritation.

Sensitization

A cellulase enzyme was not a skin sensitizer to guinea pigs (HERA, 2005).

Repeated Dose Toxicity

Male and female rats were dosed by oral gavage with 0, 300, 1,000 or 3,000 mg/kg of a cellulase enzyme for 4 weeks. There were no treatment-related clinical signs, but a slight dose-related increase in body weight gain (approx. 7%) was seen in the males. No treatment-related changes were noted in the hematology or clinical chemistry. There were no gross or histopathologic changes that were considered treatment-related (HERA, 2005).

Male and female rats were given in their feed concentrations of 0, 120, 600 or 3,000 mg/kg of a cellulase enzyme for 13 weeks. There were no treatment-related clinical signs. A reduction in body weight gain was seen in both sexes at the 3,000 mg/kg level (10% in males and 20% in females). A slight reduction in food consumption was also noted for the 3,000 mg/kg rats. Alkaline phosphatase was increased in the 600 and 3,000 mg/kg females in a dose-dependent manner. There were no gross or histopathologic changes that were considered treatment-related. The NOAEL for this study is 600 mg/kg/day (HERA, 2005).

Genotoxicity

In an *in vitro* bacterial mutation assay, a cellulase enzyme was not mutagenic to *Salmonella typhimurium* strains TA 1535, TA 100, TA 1537 and TA98 in the presence or absence of metabolic activation. In an *in vivo* bone marrow micronucleus assay, a cellulase enzyme was not genotoxic when given to rats by oral gavage (HERA, 2005).

Carcinogenicity

No data were found.

Reproductive Toxicity

No data were found.

Developmental Toxicity

No data were found.

Key Study/Critical Effect for Screening Criteria

In a 13-week dietary study, there was reduced body weight gain in rats given 3,000 mg/kg of a cellulase enzyme. No other adverse effects were observed. The NOAEL for this study is 600 mg/kg-day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability); 10 (subchronic to chronic)

Oral RfD = 600/1000 = 0.6 mg/kg-day

Drinking water guideline = 2 ppm

Toxicity Profile

Maltodextrin
(CAS No. 9050-36-6)

Maltodextrin is a nonsweet nutritive saccharide polymer that consists of D-glucose unites linked primarily by $\alpha,1\rightarrow4$ bonds and that has a dextrose equivalent (D.E.) of <20. Typical commercial maltodextrins contain as few as three and as many as nineteen linked dextrose units. It is prepared as a white powder or concentrated solution by partial hydrolysis of corn starch, potato starch, or rice starch with safe and suitable acids and enzymes.

Maltodextrin is considered to be a biopolymer that is broken down in the gastrointestinal tract to its monomeric units and absorbed. The corresponding monomers are found naturally in the body. Thus, maltodextrin is expected to be safe to human health.

The U.S. FDA lists maltodextrin as GRAS (Generally Recognized as Safe).

No toxicity data could be found on maltodextrin and therefore no oral reference dose or drinking water standard was determined.

Toxicity Profile

Polyethylene Glycol
(CAS No. 25322-68-3)

Polyethylene glycols (PEGs) are water-soluble linear polymers formed by the addition reaction of ethylene oxide to an ethylene glycol equivalent. The general formula for polyethylene glycol is: $H-(OCH_2CH_2)_n-OH$ where "n" is the average number of repeating oxyethylene groups. PEGs are available in average molecular weights ranging from 200 to 8000.

Toxicity data are available on PEG 200. PEG 200 is a mixture consisting of ethylene glycols with an average molecular weight of approximately 200; there is an average of 4 oxyethylene units, but the range is from 2 to 8 oxyethylene units. The approximate composition of PEG 200 is as follows: 3% diethylene glycol, 17% triethylene glycol, 29% tetraethylene glycol, 25% pentaethylene glycol, 16% hexaethylene glycol, 8% heptaethylene glycol, and 2% octaethylene glycol (Bailey and Koleske, 1966).

Toxicity data on the two primary constituents of PEG 200, tetraethylene glycol (tetraEG) and pentaethylene glycol (pentaEG), have also been included in this toxicity profile.

Acute Toxicity

The oral LD_{50} in rats was reported to range from 25,700 to 32,500 mg/kg (OECD, 2004) and 28,130 mg/kg (OECD, 2004). The dermal LD_{50} in rabbits ranges from 14,000 to 20,000 (OECD, 2004). No deaths were reported in rats exposed to an aerosol of 2,516 mg/m^3 PEG 200 for 6 hours (OECD, 2004).

Irritation

TetraEG was minimally irritating to human skin (OECD, 2004). PentaEG produced minor transient irritation to rabbit skin (OECD, 2004). Both tetraEG and pentaEG produced minimal transient irritation to the eyes of rabbits (OECD, 2004).

Sensitization

TetraEG was not a skin sensitizer to guinea pigs or to humans (OECD, 2004).

Repeated Dose Toxicity

No toxicity was seen in rats given 1,880 mg/kg/day PEG 200 in feed, the highest dose tested, for two years (OECD, 2004).

Genotoxicity

PEG 200 produced chromosomal aberrations *in vitro* (Biondi *et al.*, 2002). *In vivo*, the mixture was associated with significant elevations producing a dose-dependent trend for chromosome aberrations, but only in males at a single time point (12 hour harvest) in an otherwise negative two-sex, multi-time point rat bone marrow assay (OECD, 2004).

PEG 200 also contains diethylene glycol DEG), triethylene glycol (TEG), tetraEG and pentaEG; all have been tested for genotoxicity. PEG 200 also contains several glycols of higher molecular weights, which have not been assessed for mutagenicity.

Mutagenicity studies in bacteria and *in vitro* mutagenicity studies in mammalian cells have been conducted for DEG and TEG and the results have been uniformly negative (OECD, 2004). The results of *in vitro assays* of EG and DEG for chromosomal aberrations (CHO chromosomal aberration and sister chromatid exchange assays) have also been uniformly negative (OECD, 2004). DEG and TEG have not been tested *in vivo* for genotoxicity.

TetraEG has been found to cause chromosome aberrations *in vitro* (OECD, 2004); however, three assays for chromosome levels effects *in vivo* have been either negative or equivocal. These *in vivo* studies include a negative rat dominant lethal test; a negative rat bone marrow chromosome aberration test; and an equivocal mouse peripheral blood micronucleus assay (OECD, 2004). A more recent statistical reanalysis of the rat chromosome aberration study (White and Douglas, 2003; OECD, 2004) judged the overall result to be equivocal because of a marginal association and dose related trends for either sex but at different harvest times, and a significant effect of treatment limited to the lowest doses in females at the 24 hour harvest and males at the 12 hour harvest. However, inspection of the overall data from this assay show these two values to be isolated to the lowest exposure animals and the dose effect trends to be inverse, i.e. decreasing with increasing doses without evidence of cytotoxicity from treatments. The reason for the equivocal designation for the tetraEG mouse micronucleus test was a weak statistically significant increase in MN-PCE in males only at a single time point and without a dose-response.

PentaEG was not mutagenic in the Ames test or in mammalian cells *in vitro* in the CHO/HGPRT assay (OECD, 2004). A mouse bone marrow micronucleus test of crude pentaEG (70% pentaEG, 19% tetraEG) was assessed as negative by the original investigators but deemed to be equivocal after statistical reanalysis (White and Douglas, 2003; OECD, 2004) using non-parametric contingency table analyses and trend tests. However, inspection of the primary data reveals that this reanalysis was influenced by a single uncharacteristically low MN control value in one sex (females) at a single time point, indicating that the test result is biologically negative.

Carcinogenicity

There was no evidence of carcinogenicity when rats were given 1,880 mg/kg/day PEG 200 in feed for two years (OECD, 2004).

Reproductive Toxicity

Repeat dosing with tetraEG at doses up to 6,386 mg/kg-day for 14 days or 2,000 mg/kg/day for 4 weeks produced no notable changes in the histopathology of the testes and epididymides of rats (OECD, 2004).

Developmental Toxicity

No developmental effects were seen in rats dosed orally up to 10,000 mg/kg/day PEG 200 (OECD, 2004).

Key Study/Critical Effect for Screening Criteria

No toxicity was seen in rats given 1,880 mg/kg-day PEG 200 in feed, the highest dose tested, for two years (OECD, 2004). The NOAEL for this study is 1,880 mg/kg/day.

Uncertainty factors: 10 (interspecies variability); 10 (intraspecies variability)

Oral RfD: 1880/100 = 19 mg/kg/day

Drinking water guideline value = 66 ppm

Toxicity Profile

Sodium hydroxide
(CAS No. 1310-73-2)

Sodium hydroxide (NaOH) has been reviewed in the OECD-SIDS program (OECD, 2002a,b).

Sodium hydroxide (NaOH) is present in the environment as sodium (Na^+) and hydroxyl ions (OH^-). Sodium is a normal constituent of the blood and an excess is excreted in the urine. A significant amount of sodium is taken up via the food because the normal uptake of sodium via food is 3.1-6.0 g per day according to Fodor *et al.* (1999). Exposure to NaOH could potentially increase the pH of the blood. However, the pH of the blood is regulated between narrow ranges to maintain homeostasis (pH of 7.4 to 7.5) by urinary excretion of bicarbonate and via exhalation of carbon dioxide.

Acute Toxicity

An oral LD_{50} of a 1-10% solution of NaOH in rabbits was reported to be 325 mg/kg (expressed as 100% NaOH). Mortality was also observed when 1% NaOH was dosed, but in this case, the applied volume was relatively high (24 mL per kg body weight).

Irritation
